Parasitic Infections

Sheila Seed, Larry Goodyer, and Caroline S. Zeind

CORE PRINCIPLES	CHAPTER CASES
MALARIA	
1 Malaria in humans is caused by protozoan parasites of the genus Plasmodium: Plasmodium falciparum, P. vivax, P. ovale, or P. malariae. Early symptoms of malaria are nonspecific with fever present in the majority of patients, and approximately two-thirds of infected persons may experience symptoms such as headache, muscle aches and pains, and malaise.	**Case 81-1 (Question 1)**
2 Travelers with symptoms of malaria should seek medical evaluation as soon as possible. Falciparum malaria is the most severe form of malaria and has the highest mortality. Mortality is higher in those with no immunity such as travelers from non-endemic areas, while adults living permanently in the country and exposed to malaria do develop semi-immunity. Suspected or confirmed malaria, especially P. falciparum, is a medical emergency necessitating early intervention. In instances when the traveler develops a febrile illness consistent with malaria and access to medical care is not readily available, a reliable supply of malaria treatment can be self-administered presumptively as a temporary measure.	**Case 81-1 (Questions 1, 2, 3, 5)**
3 Travelers to malaria-endemic areas need to understand the risk of malaria and know how to best prevent it with mosquito-avoidance measures and chemoprophylaxis (where appropriate). Pregnant women are at greater risk for malaria and its associated complications. Women who are pregnant or likely to become pregnant should be advised to avoid travel to endemic areas if possible. If travel cannot be deferred, use of an effective chemoprophylaxis regimen is essential.	**Case 81-1 (Question 4),** **Case 81-2 (Questions 1–3),** **Case 81-3 (Question 1),** **Tables 81-1 and 81-2**
4 Several factors must be considered when selecting a chemoprophylactic drug regimen, including drug resistance, patient-specific factors, adverse effects, precautions, and contraindications.	**Case 81-1 (Question 4),** **Case 81-2 (Questions 1–3),** **Case 81-3 (Question 1),** **Tables 81-1 and 81-2**
AMEBIASIS	
1 Amebiasis is caused by Entamoeba histolytica and implicated in amebic dysentery and hepatic abscesses. Diagnosis of amebic dysentery may	**Case 81-4 (Questions 1, 2),** **Case 81-5 (Questions 1, 2),**

	include the following information: history of travel, stool and biopsy specimens, and ultrasound to exclude liver abscesses. Treatment for amebiasis calls for a combination of agents with both luminal-acting and extraintestinal effects. Amebic cyst passers and pregnant women must be treated to avoid invasive disease and transmission of the infection.	**Case 81-6 (Question 1), Case 81-7 (Question 1), Table 81-3**

GIARDIASIS

1	The signs and symptoms of giardiasis could be insidious and vague, but patients usually present with diarrhea and bulky, foul-smelling stools along with laboratory confirmation of Giardia lamblia.	**Case 81-8 (Question 1)**
2	The major treatments for giardiasis are metronidazole and tinidazole or nitazoxanide.	**Case 81-8 (Question 2), Table 81-3**

ENTEROBIASIS

1	The signs and symptoms of the infection may be subtle, but the specific diagnostic test for Enterobius vermicularis is the cellophane tape swab. Therapy for enterobiasis includes the antihelminthic agents: albendazole, pyrantel pamoate, or mebendazole (not available in the United States). Household measures to eradicate the infection need to be addressed.	**Case 81-9 (Questions 1, 2), Table 81-3**

CESTODIASIS

1	Primarily this includes Taenia saginata and Taenia solium, and symptoms of infections are nonspecific. It is critical to differentiate these two infections from other cestode infections. Praziquantel remains an effective agent for all species of Cestodes. Cysticercosis, a complication caused by the larval cysts of T. solium that may be associated with central nervous system infection (neurocysticercosis), is serious and requires separate diagnostic testing and controversial therapy. Praziquantel, which is indicated for most cestodiasis, is well tolerated.	**Case 81-10 (Questions 1, 2), Table 81-3**

PEDICULOSIS

1	Head and body lice are associated with dermatologic reactions, which can be treated with a number of agents: permethrin, pyrethrin, malathion, and ivermectin. Special attention needs to be focused on correct application procedures, drug resistance, and lice decontamination measures.	**Case 81-11 (Questions 1, 2), Table 81-3 and 81-4**

SCABIES

1	Scabies produces pruritic rash and excoriations of the interdigital area of the upper and lower limbs. Treatment includes lindane, permethrin, and crotamiton. Clothes and personal items of the infected person and family members need to laundered (>50°C) to avoid reinfection.	**Case 81-12 (Question 1), Table 81-3**

MALARIA

Epidemiology

According to World Health Organization (WHO) estimates, malaria was responsible for an estimated 214 million cases of malaria in 2015 with an estimated 438,000 deaths, which reflects an overall 60% reduction in malaria mortality rates since 2000.[1] The global malaria burden continues to be disproportionately high with approximately 89% of malaria cases and 91% of deaths in sub-Saharan Africa.[1] Within regions of high malaria transmission, children less than 5 years of age are particularly susceptible with more than two-thirds (70%) of all malaria deaths occurring in this age group.[1] Globally in children under the age of 5 years, the malaria death rate fell by 65% between 2000 and 2015. While malaria is no longer an endemic infectious disease in the industrialized countries of North America, Europe, Australia, New Zealand, and Japan, travel to malaria-endemic regions, as well as immigration and refugee migrations into non-endemic areas, have resulted in increases in the numbers of imported cases of malaria in industrialized countries.[2,3] Millions of US travelers visit malaria-endemic areas each year and approximately 1,500 cases of malaria are diagnosed in the United States annually, mostly in returned travelers.[4]

Distribution of Malaria Species

Malaria in humans is caused by protozoan parasites of the genus Plasmodium: Plasmodium falciparum, P. vivax, P. ovale, or P. malariae.[5] The distribution of the four Plasmodium species of malaria varies worldwide. However, the vast majority of imported cases are caused by P. falciparum or P. vivax[2]; the proportion of imported cases caused by P. falciparum or P. vivax within a country reflects both the destinations that travelers select and, to a larger degree, the nature of immigrant communities.[2] In most countries, only 5% or less of malaria cases are caused by P. ovale and P. malariae.[2] In addition, P. knowlesi, a species normally found in monkeys, has been documented as a cause of human infections and some deaths in forest fringe areas of Southeast Asia.[5]

Life Cycle of the Malaria Parasite and Transmission

The life cycle of the malaria parasites in the human host is complex. All species are transmitted by the bite of an infective female Anopheles mosquito that carries malaria-causing parasites and injects the asexual forms or sporozoites into the human bloodstream. Over a period of 5 to 16 days (depending on the species), the sporozoites grow, divide, and produce daughter cells, or merozoites, per liver cell.

Infections caused by P. vivax and P. ovale may remain in a dormant stage for extended periods of time within the liver (hypnozoites) and cause relapses by invading the bloodstream for months or years later. The merozoites exit the liver cells and reenter the bloodstream and begin a cycle of invading red blood cells and asexual replication, thus producing and releasing newly formed merozoites from the red blood cells. Through this process symptoms can develop 1 week after being bitten by an infected mosquito, though in falciparum malaria this can occur up to 3 months or occasionally longer. The characteristic malarial paroxysms of chills and fever usually coincide with the periodic release of merozoites and other pyrogens in the blood. In P. falciparum infections, this periodicity may not always be apparent. A subpopulation of merozoites differentiate into sexual forms of the parasite, resulting in male and female gametocytes that circulate in the bloodstream (Fig. 81-1). If the gametocytes in the host blood are ingested by a female Anopheles mosquito during a blood meal, fertilization and an asexual division in the mosquito midgut occurs where they develop into oocysts. Each oocyst grows and divides, producing thousands of active haploid forms, called sporozoites; once mature the oocyte bursts, releasing sporozoites, making their way to the mosquitos's salivary glands. Inoculation of the sporozoites into a new human host perpetuates the malaria life cycle.

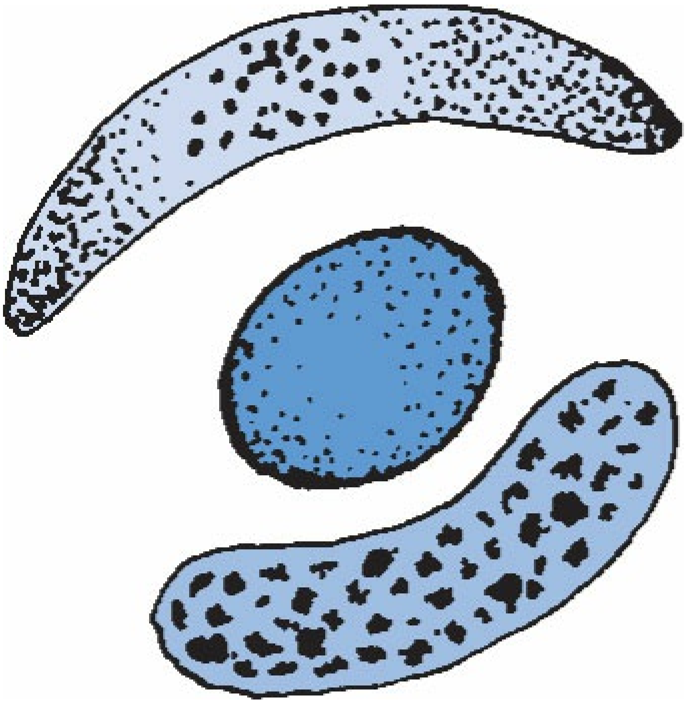

Figure 81-1 Plasmodium falciparum gametocytes.

While the majority of cases of malaria are transmitted by the bite of an infective female Anopheles mosquito, occasional transmission has occurred by blood transfusion, needle sharing, organ transplantation, or congenitally from mother to fetus.[2]

Drug Resistance

The development of drug resistance has emerged as one of greatest threats to malaria control.[1,2] Resistance to antimalarial drugs has been confirmed for two malaria species, P. falciparum and P. vivax, while the development of drug resistance is currently unknown for P. malariae or P. ovale. Of note, there have been two cases of chloroquine-resistant P. malariae reported from Indonesia, though the clinical significance remains undefined.[6]

Chloroquine-resistant P. falciparum (CRPf) has become widespread and is now found throughout most malaria-endemic areas, including all of sub-Saharan Africa, South America, the Indian subcontinent, Southeast Asia, and Oceania. Presently, CRPf, is not found in Mexico, the Caribbean, Central America, Argentina, and parts of the Middle East.[7] P. falciparum resistance has also developed to nearly all of the other currently available antimalarial agents, such as sulfadoxine/pyrimethamine, mefloquine, halofantrine, and quinine, along with the emergence of resistance to artemisinin derivatives in parts of Southeast Asia. In some parts of the world, the impact of multidrug-resistant malaria can be extensive.

Chloroquine-resistant P. vivax has also emerged as a global public health concern. First identified in 1989 among Australians living in or traveling to Papua New Guinea, chloroquine-resistant P. vivax has now been identified also in Southeast Asia, on the Indian subcontinent, and in South America. Since these areas are also co-endemic for CRPf, this has had minimal impact on chemoprophylactic recommendations because the antimalarial choice for these areas is not chloroquine.[3]

There are several online resources available to retrieve updated malaria information and country-specific risks from several sources, including the Centers for Disease Control and Prevention (CDC) and WHO.[1,3]

Acute Malaria

SIGNS AND SYMPTOMS

CASE 81-1

QUESTION 1: M.T., a 27-year-old male college student, presents to the emergency department (ED) with complaints of malaise, myalgia, headache, and fever of 5 days' duration. A native of Ghana, West Africa, he recently visited his parents who live in a remote area of Ghana, and he returned home to the United States 4 weeks ago. Two days prior to admission to the ED, he had an abrupt onset of coldness and chills, followed 1 hour later by a high fever, sweating, headache, nausea, and vomiting. The episode of chills and fever lasted about 24 hours, after which he became asymptomatic. On the afternoon of admission, he had another bout of chills that preceded a fever of 40°C.

When interviewed for his medical and travel history, he mentioned that he did not take malaria prophylaxis because he thought that he was protected since he was born and raised in Ghana and then as a teenager moved to the United States to live with relatives and to attend school. He also did not use mosquito-avoidance measures during his recent trip to Ghana.

Physical examination reveals a slender black man who is acutely ill and complaining of severe abdominal pain. Abdominal examination reveals a soft, tender spleen that is slightly enlarged. Blood pressure (BP) is 110/70 mm Hg; pulse, 120 beats/minute; respiration rate, 32 breaths/minute with crackles on pulmonary auscultation; and temperature, 40°C. Laboratory findings include the following:

Hemoglobin (Hgb), 11 g/dL
Hematocrit (Hct), 34%
White blood cell (WBC) count, 5,300 cells/μL with 76% neutrophils (normal, 45%–65%), 23% lymphocytes (normal, 15%–35%), and 1% monocytes. Platelets 26,000/microliter
Creatinine 1.5 mg/dL
CRP 228.9 mg/dL
Bilirubin, 1.0 mg/dL

Urinalysis reveals trace amounts of albumin and the presence of urobilinogen. Thick and thin films of M.T.'s blood are prepared and a parasitemia of 20% is reported. A Giemsa stain of the thin film demonstrates P. falciparum gametocytes.

Describe how M.T.'s presentation is consistent with P. falciparum malaria and explain his risk factors.

M.T. recently visited Ghana, West Africa, where P. falciparum is endemic. The incubation period ranges between 1 week and 3 months, though it may occur later in rare cases.[8,9] Early symptoms of malaria are nonspecific with fever presenting in most patients and is often accompanied by rigors, as in M.T.'s presentation. Approximately two-thirds of infected persons usually experience symptoms such as headache, muscle aches and pains, and malaise, while about one-third of patients experiencing dry cough in the absence of other respiratory symptoms, diarrhea, and other gastrointestinal (GI) symptoms.[6] M.T.'s presentation is consistent with the majority of malaria-infected travelers because approximately 90% of them do not become symptomatic until they return home.[10–12] Given the nonspecific symptomatology with malaria, it is important that a good travel history is obtained as part of the evaluation. M.T.'s history of travel to an endemic area, the cyclical paroxysmal episodes of chills and fever, the presence of thrombocytopenia, abdominal pain, splenomegaly, and the identification of P. falciparum gametocytes in M.T.'s blood confirm the diagnosis of malaria.

Because M.T. grew up in Ghana in his early years but has been living for over a decade in the United States (a non-endemic country), he is considered to be in a high-risk group known as "travelers visiting friends and relatives" or VFR travelers.[13] When he returned to Ghana, an endemic country, to visit his parents, his loss of immunity over a period of time, placed him in a high-risk group for malaria. Unfortunately, M.T. neglected to take malaria chemoprophylaxis because he thought his risk was low. Healthcare providers should raise awareness of the importance for malaria prophylaxis as well as other prevention strategies for VFR travelers.

TREATMENT

CASE 81-1, QUESTION 2: How should P. falciparum malaria in M.T. be treated?

Unfortunately, M.T. has acquired falciparum malaria, the most severe form of malaria with the highest mortality rate. Thus, M.T.'s treatment is a medical emergency, requiring immediate attention as mortality correlates with diagnostic and therapeutic delay.[8] M.T. would be classified as having a severe case of malaria with complications, which could result in organ damage, including cerebral malaria. This is a particular feature of P. falciparum which unlike the other forms causes red blood cell adhesion to blood vessel walls causing local damage and ischemia to end organs. His clinical symptoms along with the results of 20% parasitemia support a severe case of falciparum malaria.

Specific treatment guidelines for treatment of malaria in the United States are provided by the Centers for Disease Control and Prevention (CDC)[14] at http://www.cdc.gov/malaria/diagnosis_treatment/treatment.html and by the World Health Organization[15] available at http://www.who.int/malaria/publications/atoz/9789241549127/en/.

Because M.T.'s condition is critical, he should be admitted to an acute care unit and started on intravenous (IV) artesunate for at least 24 hours. According to WHO guidelines for severe malaria, intravenous or intramuscular artesunate is the drug of choice for treatment of severe malaria because it has demonstrated a greater reduction in mortality compared with parenteral quinine.[15] Many hospitals/institutions no longer stock intravenous quinidine gluconate for treatment of malaria and if used the drug requires careful cardiac monitoring. Parenteral artesunate can be obtained from the CDC (Malaria Hotline: 770-488-7788 or toll-free 855-856-4713 or after hours at 770-488-7100 for malaria clinician on call) as an investigational drug (IND). If parenteral artesunate is not available, an alternative agent would be the use of intramuscular artemether, which is preferred over the use of quinine for treatment of adults and children with malaria.

Once M.T. has received at least 24 hours of parenteral therapy and is able to tolerate oral therapy, he would complete 3 days of therapy with an artemisinin-based combination therapy (ACT), such as artemether–lumefantrine (Coartem). The artemisinin component is effective at rapidly clearing parasites from the blood. If an ACT is unavailable, other options can be used: artesunate + clindamycin, artesunate + doxycycline, quinine + clindamycin, or quinine + doxycycline, though tolerability and side effects of quinine are problematic. The risk of death is greatest within the first 24 hour, requiring careful monitoring for management of complications as well as supportive care.

Managing Other Plasmodium Species

CASE 81-1, QUESTION 3: How would M.T.'s treatment of malaria differ if it had been a different

Plasmodium species?

If M.T. had been infected with one of the other species of Plasmodium (P. vivax, P. ovale, or P. malariae) treatment with an ACT for 3 days would be considered first-line treatment for all species.[15] This approach will provide sufficient efficacy for malaria treatment, promote good medication adherence, and minimize the risk of drug resistance. There are five ACTs recommended for the treatment of uncomplicated malaria:

- artemether + lumefantrine
- artesunate + amodiaquine
- artesunate + mefloquine
- artesunate + SP (sulfadoxine-pyrimethamine)
- dihyroartemisinin + piperaquine

It is important to check for chloroquine-resistant regions such as chloroquine-resistant P. vivax, which has been documented in Papua New Guinea and Indonesia, Brazil, Columbia, Ethiopia, Guatemala, Guyana, India, Myanmar, Peru, the Republic of Korea, Solomon Islands, Thailand, and Turkey.[8,16]

Patients with P. ovale and P. vivax should also be given primaquine to prevent relapses from the latent exoerythrocytic stages in the liver.[2] Before primaquine is used in any patient, glucose-6-phosphate dehydrogenase (G6PD) deficiency must be ruled out by laboratory testing because it can cause hemolysis that can be fatal in G6PD-deficient individuals.

PREVENTION OF MALARIA

CASE 81-1, QUESTION 4: What malaria chemoprophylaxis recommendation would have been options for M.T. prior to his travel to visit his parents in Ghana? Provide guidance to M.T. regarding antimalarial options, adverse effects, counseling parameters, and mosquito-avoidance measures.

Travelers to malaria-endemic areas, such as M.T., should receive malaria prophylaxis and should follow mosquito-avoidance measures.[7] The goal of malaria prevention is to prevent malaria caused not only by P. falciparum but also by all species. It is important to assess an individual's level of risk, which includes the destination country, the detailed itinerary, including specific activities (e.g., back-packing in the wilderness), types of accommodations, and style of travel. Pregnancy, lactation, and other conditions, HIV disease, other immunocompromised diseases, as well as drug resistance at the destination will impact the risk assessment.

Because M.T. is a first-generation immigrant living in a non-endemic country and was returning to Ghana, his country of origin, as a VFR traveler he was considered at high risk for contracting malaria. Recommendations for drugs used for malaria prophylaxis are provided by the CDC[17] at **https://wwwnc.cdc.gov/travel/yellowbook/2018/infectious-diseases-related-to-travel/malaria#3-10-chlor**

Given M.T.'s travel destination to Ghana with P. falciparum estimates at 90%, appropriate options for malaria prophylaxis are atovaquone–proguanil, doxycycline, or mefloquine. It is important that M.T. understands the differences in the agents, including proper administration, their adverse effect profile, and potential drug interactions. Table 81-1 provides a summary of the various agents for malaria prophylaxis and highlights adverse effects, contraindications, precautions, and potential drug interactions.[5,7,18] The importance of beginning chemoprophylaxis prior to travel should be emphasized. While medications for malaria prophylaxis may be available at the destination location, travelers are strongly discouraged from obtaining chemoprophylaxis medications while abroad because the quality of these products are not known. These products may be counterfeit or may have been manufactured using substandard manufacturing practices or may contain contaminants.[19,20]

Table 81-1

Antimalarial Drugs Used for Malaria Prophylaxis

Drug	Usage	Adverse Effects	Contraindications and Precautions	Drug Interactions
Atovaquone–proguanil (fixed drug combination)	Prophylaxis in all areas Begin 1–2 days before travel to malarious areas Take daily (same time each day) while in malarious area and for 7 days after leaving such areas Take with food or a milky drink In the United States and European Union, a pediatric formulation is available (quarter strength = 62.5 mg atovaquone and 25 mg proguanil). CDC sanctions atovaquone/proguanil for infants >5 kg. WHO allows use in infants weighing >11 kg	Nausea, vomiting, abdominal pain, increased transaminase, seizures, and rash	Contraindicated in severe renal impairment (creatinine clearance <30 mL/minute) Not recommended in pregnancy or breastfeeding (use only during pregnancy if potential benefits of therapy outweigh potential risk to infant)	Tetracycline, rifampin, and rifabutin significantly decrease atovaquone level (avoid concurrent use) May interact with antiretroviral protease inhibitors ritonavir, darunavir, atazanavir, indinavir, and lopinavir, in addition to the non-nucleoside reverse transcriptase inhibitors nevirapine, etravirine, and efavirenz; monitor when used Metoclopramide: may reduce bioavailability of atovaquone; avoid use of this agent as

	Partial doses may need to be prepared by a pharmacist and dispensed in capsules			an antiemetic to treat vomiting that may occur with atovaquone at treatment doses Avoid use with cimetidine and fluvoxamine because of interference with proguanil's metabolism
Chloroquine phosphate	Prophylaxis only in areas with chloroquine-sensitive malaria Begin 1–2 weeks before travel to malarious areas. Take weekly (same day of the week) while in malarious area and for 4 weeks after leaving such areas Chloroquine sulfate (Nivaquine) is not available in the United States and Canada, but it is available in most malaria-endemic countries in both tablet and syrup forms	May exacerbate psoriasis; pruritus in black-skinned individuals, nausea, headache, skin eruptions, reversible corneal opacity, nail and mucous membrane discoloration, nerve deafness, photophobia, myopathy, retinopathy with daily use, blood dyscrasias, psychosis, seizures, and alopecia	Contraindications: Persons hypersensitive to 4-aminoquinoline compounds and in G6PD-deficient individuals (hemolysis is rare when given at prophylactic and therapeutic doses) Preexisting retinopathy, diseases of the central nervous system, myasthenia gravis, disorders of the blood-producing organs, a history of epilepsy or psychosis Dosage reduction may be required: hepatic function impairments	May increase risk of prolonged QTc interval when given with other QT-prolonging agents (e.g., sotalol, amiodarone, and lumefantrine); antiretroviral rilpivirine prolongs QTc; avoid combination of chloroquine with any of these agents Chloroquine inhibits CYP2D6 and when used concomitantly with substrates of this enzyme (e.g., metoprolol, propranolol, fluoxetine, paroxetine, and flecainide); increase monitoring for side effects Chloroquine absorption may be reduced by antacids or kaolin; space apart by ≥4 hours Avoid concomitant use of cimetidine and chloroquine as cimetidine can inhibit chloroquine's metabolism; avoid concurrent use of CYP3A4 inhibitors such as ritonavir, ketoconazole, and erythromycin as they may increase

				chloroquine levels Chloroquine may increase digoxin levels, requiring careful monitoring Use with caution with calcineurin inhibitors as their levels may be increased by chloroquine Chloroquine inhibits bioavailability of ampicillin; space apart doses by 2 hours. Chloroquine may decrease the bioavailability of ciprofloxacin and methotrexate

---

Doxycycline	Prophylaxis in all areas Begin 1–2 days before travel to malarious areas Take daily at the same time each day while in the malarious area and for 4 weeks after leaving such areas	GI upset (nausea, vomiting, abdominal pain, and diarrhea (less frequent than with other tetracycline agents); esophageal ulceration; vaginal candidiasis, photosensitivity, allergic reactions, blood dyscrasias, azotemia in renal diseases, and hepatitis	Contraindicated in children aged <8 years and in pregnant women Breastfeeding: excreted into breast milk; may cause permanent discoloration of teeth, damage to tooth enamel, impairment of skeletal growth, and photosensitivity in breastfed infants	Phenytoin, carbamazepine, and barbiturates may decrease doxycycline’s half-life Anticoagulants: may require reduction in anticoagulant dose while taking doxycycline; close monitoring of prothrombin time Absorption may be impaired by concomitant ingestion of bismuth subsalicylate, preparations containing iron, calcium, magnesium, or aluminum; avoid taking these preparations within 3 hours of taking doxycycline Doxycycline may interfere with

				bactericidal activity of penicillin; avoid use of both drugs together
Hydroxy-chloroquine sulfate	An alternative to chloroquine for prophylaxis only in areas with chloroquine-sensitive malaria			
Mefloquine	Prophylaxis in areas with mefloquine-sensitive malaria Begin ≥2 weeks prior to travel to malarious areas Take weekly on the same day of the week while in the malarious area and for 4 weeks after leaving such areas Travelers should receive a copy of the FDA Medication Guide when receiving a prescription for mefloquine	Dizziness, diarrhea, nausea, vivid dreams, nightmares, irritability, mood alterations, headache, insomnia, anxiety, seizures, and psychosis	Contraindicated in persons allergic to mefloquine or related compounds (quinine, quinidine) and in persons with active depression, a recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures Caution: in persons with psychiatric disturbances or a previous history of depression Not recommended for persons with cardiac conduction abnormalities Use with caution or avoid in individuals taking antiarrhythmic or β-blocking agents, calcium channel blockers, antihistamines, H1-blocking agents, tricyclic antidepressants, or phenothiazines Use in second and third trimesters in pregnancy for women who cannot defer travel to high-risk areas is sanctioned by manufacturer, CDC, and WHO Breastfeeding: small	May interact with antimalarial drugs that alter cardiac conduction; increased toxicities with lumefantrine (available in United States in fixed combination to treat uncomplicated P. falciparum malaria); avoid or use with caution because of potentially causing fatal prolongation of the QTc interval May lower plasma concentrations of anticonvulsant agents, such as valproic acid, carbamazepine, phenobarbital, and phenytoin; avoid concurrent use May increase levels of calcineurin inhibitors and mTOR inhibitors (tacrolimus, cyclosporine A, and sirolimus) Potent CYP3A4 inhibitors (e.g., clarithromycin, erythromycin, ketoconazole, voriconazole, and itraconazole, ritonavir, lopinavir, darunavir, atazanavir, and cobicistat) may increase the levels

			amounts secreted in breast milk; effect on breastfed infants is unknown	of mefloquine, increasing the risk of QT prolongation CYP3A4 inducers (e.g., efavirenz, nevirapine, etravirine, rifampin, and rifabutin) may reduce plasma concentrations of mefloquine and concurrent use should be avoided Avoid concurrent use with agents boceprevir and telaprevir (drugs used to treat hepatitis C)

Primaquine	Prophylaxis for short-duration travel to areas with principally P. vivax Used for presumptive antirelapse therapy (terminal prophylaxis) to decrease the risk for relapses of P. vivax and P. ovale Start therapy 1–2 days before travel to malarious areas Take daily at the same time each day while in the malarious area and for 7 days after leaving such area A documented normal G6PD level should be obtained prior to starting primaquine therapy	GI upset; hemolysis in G6PD deficiency, methemo-globinemia	Contraindicated in individuals with G6PD deficiency (G6PD level should be obtained prior to starting primaquine therapy as G6PD deficiency must be ruled out by laboratory testing). Contraindicated during pregnancy and lactation (unless the infant being breastfed has a documented normal G6PD level)

CDC Health Information for International Travel 2016. New York, NY: Oxford University Press; 2016:54–57; Schlagenhauf P, Kain KC. Malaria prophylaxis. In: Keystone JS et al, eds. Travel Medicine. 3rd ed. Philadelphia, PA: Saunders Elsevier; 2013:146–147.

M.T. should be counseled regarding mosquito-avoidance measures, not only for malaria but also for protection against Aedes mosquitos (transitions of dengue, chikungunya, and the Zika viruses). Because malaria transmission occurs primarily between dusk and dawn, contact with mosquitos can be reduced by remaining in well-screened areas, using mosquito bed-nets (preferable insecticide-treated nets), using insecticide sprays, wearing clothes that cover most of the body, and treating clothing with permethrin. Table 81-2 summarizes strategies to optimize protection against mosquitos and items that travelers can include in a travel kit for malaria prevention.[21,22] In addition to mosquito-avoidance measures, it is important to emphasize to travelers, such as M.T., to inspect themselves and their clothing for ticks during outdoor activity and at the end of the day (see Chapter 82, Tick-Borne Diseases for further information).

STANDBY EMERGENCY TREATMENT

Given the risk of complications and deaths because of the delay initiating treatment of malaria, the concept of standby emergency treatment (SBET) was introduced in the late 1980s and then updated to provide travelers with a treatment dose of an appropriate antimalarial drug to be carried and taken in case of a febrile illness, when prompt medical attention is unavailable within 24 hours following the onset of symptoms.[23–25] The major issue with SBET is the difficulty for travelers to make a self-diagnosis of malaria based on clinical symptoms. For those situations in which the traveler does not have access to medical care and develops a febrile illness with symptoms consistent with malaria, a supply of medications could be administered presumptively until medical evaluation is available.

CASE 81-1, QUESTION 5: Would M.T. have been a candidate for SBET prior to his trip to Ghana?

In the United States, two malaria treatment regimens are available that could be prescribed for self-treatment: atovaquone–proguanil and artemether–lumefantrine. Because M.T. was traveling to a remote region in Ghana, discussing this option with a travel health provider would have been important in preparation for his trip. M.T. is a good candidate for SBET and could have taken a reasonable supply of a full-course of an approved malaria treatment regimen with him on his trip. It is important to note that the use of the same or related drugs that are taken for prophylaxis are not recommended to treat malaria. Thus, if M.T. was taking a reliable supply of atovaquone–proguanil as SBET, then atovaquone–proguanil would not be selected for malaria prophylaxis. Either mefloquine or doxycycline would be acceptable choices for malaria prophylaxis.

The introduction of rapid diagnostic tests (RDTs), which are based on the immunochromatographic detection of plasmodial proteins, has become an important component of the current global malaria control strategies, alongside ACTs for falciparium malaria across most areas of endemicity. The use of RDTs is being evaluated as a tool for self-use by travelers to determine if it will help them decide whether or not to use SBET.[23] Future directives will continue to evaluate the feasibility and utility of RDTs in providing guidance to travelers on whether to initiate SBET.

CASE 81-2

QUESTION 1: J.P., a 35-year-old male who owns a small business in the United States, is planning to visit his seriously ill grandmother who lives in eastern region of Indonesia. J.P. immigrated to the United States when he was 20 years old, and he has not previously had a chance to go back to Indonesia. Given his concern for his grandmother's health, his wife, R.T., who is 24 weeks pregnant, wants to join him and also bring their 6-year-old daughter. R.T. is also from Indonesia and moved to the United States 8 years ago. Assess the malaria risks of each member of the family.

Table 81-2

Mosquito Protection Measures

Protective Measures		Comments
Clothing	Wear a long-sleeved shirt, long pants, and socks Treat clothing with permethrin 24–48 hours prior to travel to allow them to dry or purchase pretreated clothing	Permethrin-treated clothing will retain repellant activity through multiple washes Repellants used on skin can also be applied to clothing and must be reapplied after laundering Clothing treated with other repellent products (e.g., DEET) provides protection from biting arthropods but will not last through washing and will require more frequent reapplications
Insecticides	Permethrin: highly effective insecticide–acaricide and repellent	
Repellents for use on skin and clothing	Apply lotion, liquid, or spray repellent to exposed skin Ensure adequate protection during times of the day when mosquitos are most active (malaria vector mosquitos bite mainly from dusk to dawn) Reapply repellants as protection wanes and mosquitos start to bite Purchase repellents before traveling	Repellents may be used with sunscreen. General recommendation: use separate products, applying sunscreen first and then applying the repellent. Combination sunscreen and repellent products are not recommended, because sunscreen may need to be reapplied more frequently and in larger amounts than repellents Travelers may need to reapply sunscreen more often as limited data show a one-third decrease in the sun protection factor of sunscreens when DEET-containing insect repellents are used after a sunscreen is applied
	DEET (chemical name: N,N-diethyl-m-toluamide or N,N-diethyl-3-methyl-benzamide) DEET formulations worldwide: concentrations range from 5%	Gold standard of insect repellents for several decades In the United States registered for use by the general public since 1957 Can be applied to skin, clothing, mesh insect nets or shelters, window screens, tents, or sleeping bags

	to 100%. For most activities, 10%–35% DEET will usually provide adequate protection	
	Picaridin (KBR 3-23 [Bayrepel] and Picaridin outside of the United States; chemical name: 21-(2-hydroxyethylo)-1-piperidinecarboxylic acid 1-methylpropyl ester)	
	Oil of lemon eucalyptus (OLE) or PMD (chemical name: para-menthane-3,8-diol). The synthesized version of OLE.	Note that EPA-registered repellent products contain the active ingredient OLE (or PMD). “Pure” oil of lemon eucalyptus (essential oil is not formulated as a repellent) and not recommended because it has not undergone validated safety and efficacy testing and is not registered with the EPA as an insect repellent.
	IR3535 (chemical name: 3-[N-butyl-N-acetyl]-aminopropionic acid, ethyl ester).	

EPA, Environmental Protection Agency.

Protection against mosquitoes, ticks, & other arthropods. In: Centers for Disease Control and Prevention. CDC Health Information for International Travel 2016. New York, NY: Oxford University Press; 2016:94–99; Schlagenhauf P, Kain KC. Malaria prophylaxis. In: Keystone JS et al, eds. Travel Medicine. 3rd ed. Philadelphia, PA: Saunders Elsevier; 2013:143–144.

Malaria prevention strategies for both short-term and long-term travelers consist of a combination of mosquito-avoidance measures and chemoprophylaxis. It is important to assess the individual risk of each traveler, including a detailed itinerary of the specific cities, types of accommodations, and activities (e.g., backpackers, adventure travelers).

Similar to the previous case of M.T., (Case 81-1) VFR travelers, such as J.P. and R.T., are at high risk because they are first-generation immigrants living in non-endemic countries who are returning to their countries of origin. They may consider themselves to be at no risk because they were raised in a malarious country (Indonesia) and consider themselves immune. They should be advised that any acquired immunity is lost quickly and they are considered to have the same risk as nonimmune travelers. Because R.T. is pregnant, she should be advised that malaria infection in pregnant women can be more severe with increased risk for adverse pregnancy outcomes than in nonpregnant women. In particular, falciparum malaria acquired during pregnancy has been associated with an increased risk of miscarriage and still birth, intrauterine growth retardation, as well as other complications, and maternal mortality.[7] She should be advised to avoid travel to eastern Indonesia because it is an endemic region. Their 6-year-old daughter should also follow preventive measures because infants, children, and adolescents of any age can contract malaria and they are traveling to a malarious region.

CASE 81-2, QUESTION 2: J.P. and his wife R.T. have not finalized their decision if they will travel together to visit J.P.'s grandmother, and bring their daughter. They want to learn more about resources available to them and options for malaria prevention for this trip, so that they can weigh the risks and benefits of traveling to Indonesia.

In eastern Indonesia, including Papua New Guinea, chemoprophylaxis is recommended for J.P. and his family that will protect them against CRPf infections. The CDC Health Information for International Travel[26] (commonly referred to as the Yellow Book) serves as a useful resource for both travelers and clinicians regarding updated information on parasitic diseases and immunization requirements. In addition, travelers such as J.P. and his wife and clinicians can select the type of traveler on the program menu, which in their case they would select "traveling with children," "visiting friends or family," and also the "pregnant women" categories, which will provide them with additional relevant information for their special needs. In addition the CDC Malaria Hotline, mentioned previously provides malaria support. Other useful resources include the Morbidity and Mortality Weekly Reports and the WHO.

Non-Falciparum Prophylaxis

It is important to note that nearly all P. falciparum is chloroquine resistant and P. vivax and P. falciparum are the two most common encountered in travelers to eastern Indonesia (refer to section that follows for prophylaxis for P. falciparum). There have been reports confirming a high prevalence of chloroquine-resistant P. vivax in Papua New Guinea or Indonesia.[14] Therefore, antovaquone–proguanil, doxycycline, or mefloquine would be recommended as options for treatment, and mefloquine would be the appropriate choice during pregnancy. In addition, infections with P. vivax and P. ovale can relapse as a result of hypnozoites that remain dormant in the liver. Therefore, a 14-day course of primaquine therapy is recommended with appropriate screening for G6PD deficiency prior to treatment. Primaquine should be avoided during pregnancy.

Prophylaxis for Plasmodium falciparum

There are three broadly equally effective prophylactics for most regions where there is P. falciparum—atovaquone–proguanil, doxycycline, and mefloquine. Selection of an antimalarial agent depends on individual factors, patient preference regarding the regimen, the side effect profile, and contraindications (see Table 81-1).

Prophylaxis for P. falciparum can be achieved by taking the combination of atovaquone and proguanil administered once daily 1 to 2 days before entering malarious areas, continued for the duration of malaria exposure, and for 1 week after return. Mefloquine should be taken beginning at least 1 week prior to entering malarious areas, and continuing through 4 weeks after leaving the endemic area. A third option is doxycycline beginning 1 day before entering malarious areas, continued for the duration of the stay, and for 4 weeks after leaving the malarious area.

In pregnant patients, such as R.T., traveling to CRPf areas, mefloquine is the only medication recommended for malaria prophylaxis during pregnancy. Atovaquone–proguanil is not recommended for use during pregnancy because data are still lacking to fully evaluate its safety, and doxycycline is contraindicated. Given the prevalence of P. falciparum and P. vivax in eastern Indonesia, chloroquine would not be recommended and mefloquine would be an appropriate option for R.T. who is in her second trimester. As mentioned above, P. vivax resistance would also be a concern for travel to eastern Indonesia, and mefloquine would provide appropriate coverage.

Given the risks of acquiring malaria during pregnancy, J.P. and R.T. should reconsider their decision to travel together. With regard to their 6-year-old daughter, mefloquine and atovaquone–proguanil are options as doxycycline is contraindicated in children less than 8 years of age. Practical advice should be emphasized, including physical barriers (e.g., clothes, mosquito nets), insect repellent, and minimizing the stay in the endemic area also decrease the likelihood of transmission. Table 81-2 summarizes strategies to optimize protection against mosquitos and items that travelers can be advised to include in a traveler kit for malaria prevention. Considerations when selecting a drug for malaria prophylaxis are available by the CDC[17] at **http://wwwnc.cdc.gov/travel/yellowbook/2018/infectious-diseases-related-to-travel/malaria**.

MALARIA VACCINE

CASE 81-2, QUESTION 3: Could J.P. be vaccinated as an alternative to chemoprophylaxis?

Currently, no malaria vaccine is available because there have been numerous challenges in the development of a vaccine, including the technical complexity of developing a vaccine against a parasite and the lack of a traditional market.[27] As a result of successful in vitro P. falciparum cultivation and advances in genetic engineering and monoclonal antibody research, some progress has been made, but this vaccine is years from approval. The malaria parasite undergoes many transformations during its development, and each stage expresses a different plasmodial genome that generates a large number of antigens. The development of a malaria vaccine relies on the identification and characterization of these antigens and the subsequent production of monoclonal antibodies. Presently there are over a dozen vaccine candidates in clinical development that are being evaluated. A Malaria Vaccine Technology Roadmap has been designed by leading global health organizations that is focused on accelerating the development of a highly effective malaria vaccine.

CASE 81-3

QUESTION 1: C.S., a 29-year-old female, comes to the community pharmacy with a prescription for mefloquine that she obtained from a local travel medicine clinic. She explains that she will be traveling to sub-Saharan Africa for 6 weeks with a group of female friends, and she is concerned about experiencing adverse effects to mefloquine while she is on her 1-month safari trip. She also wants your advice regarding malaria prevention. She currently takes an oral contraceptive and also a multivitamin daily and has no known drug allergies. Provide guidance to C.S. regarding mefloquine and advice on approaches to malaria prevention.

It is important to consider patient-specific factors in C.S. and drug-related factors. Given her concerns, C.S. can be advised to start early with mefloquine prophylaxis (2.5–3 weeks before her trip), which will be taken weekly on the same day.[7] This will allow her to assess her tolerability to mefloquine as the majority of adverse effects occur within the first three doses. If there are any tolerability issues that occur, this will enable her to switch to another agent.

In terms of overall malaria prevention strategies, the importance of adherence to malaria prophylaxis should be emphasized, because C.S. will begin mefloquine prior to her trip and will continue therapy while she is in the malarious region, and for 4 weeks after leaving the area. Personal protection measures should be reviewed with C.S., including habitat avoidance, the use of insect repellants, protective clothing, and bed-nets (see Table 81-2).[21,22] For example, if C.S. selects a product containing DEET (N,N-diethyl-m-toluamide or N,N-diethyl-3-methylbenzamide), she should be counseled on using a sunscreen product separately (rather than a combination product). Sunscreen may need to be reapplied more often and in larger amounts than the insect repellent because limited data has shown a one-third decrease in the sun protection factor of sunscreens when DEET-containing insect repellents are used after a sunscreen is applied.[22]

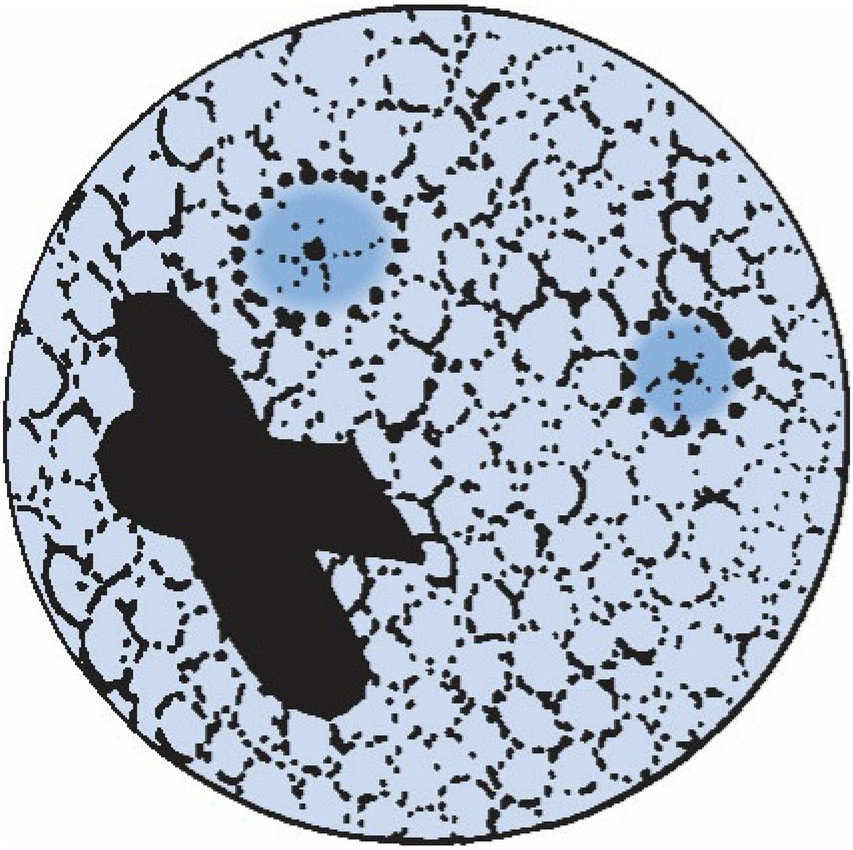

Figure 81-2 Entamoeba histolytica.

AMEBIASIS

Prevalence and Mortality

Amebiasis is an infection caused by the intestinal protozoan parasite Entamoeba histolytica (Fig. 81-2), resulting in diarrhea or amebic dysentery. Extraintestinal infections may occur when the parasite spreads to other organs, the most common being the liver, resulting in hepatic abscesses.[28,29] This parasitic infection is distributed globally, affecting more than 50 million people with over 100,000 deaths annually.[30] Those most affected are people living in, traveling to, or recent immigrants from endemic areas where there are suboptimal sanitary conditions, particularly in tropical or subtropical developing countries. Transmission occurs by the fecal–oral route via direct person-to-person contact or by consumption of contaminated food and water.[31] Risk factors include poor sanitary conditions, anal sexual exposure, and household contact with an infected person. Most individuals are infected with E. dispar (80%) or E. moshkovskii, which are antigenically different strains from the pathogenic E. histolytica (10%) and do not cause symptomatic invasive disease.[32,33] Amebiasis can be asymptomatic, or it may present as colitis or dysentery. Extraintestinal lesions include abscesses in the liver, lungs, skin, and, rarely, the brain.[28,29,31–33]

Life Cycle

Infection occurs by ingestion of mature cysts present in fecally contaminated water or food. Excystation occurs in the lumen of the small intestines where eight trophozoites are released from one cyst and migrate to the large intestine (Fig. 81-3). Trophozoites multiply by binary fission. In noninvasive infections, trophozoites remain in the intestinal lumen. In invasive infections, trophozoites invade the intestinal mucosa producing ulcerations, resulting in amebic dysentery.[34] Trophozoites may enter the bloodstream traveling to the liver, and in rare instances to the brain, lungs, and genitals forming abscesses. Both trophozoites and cysts are passed in the feces of an infected individual. Trophozoites do not survive outside the host body, if ingested they will be destroyed by gastric juices. The cyst form can survive days to weeks in the external environment, only killed by temperatures in excess of 55°C or hyperchlorinated water.[32,33,35]

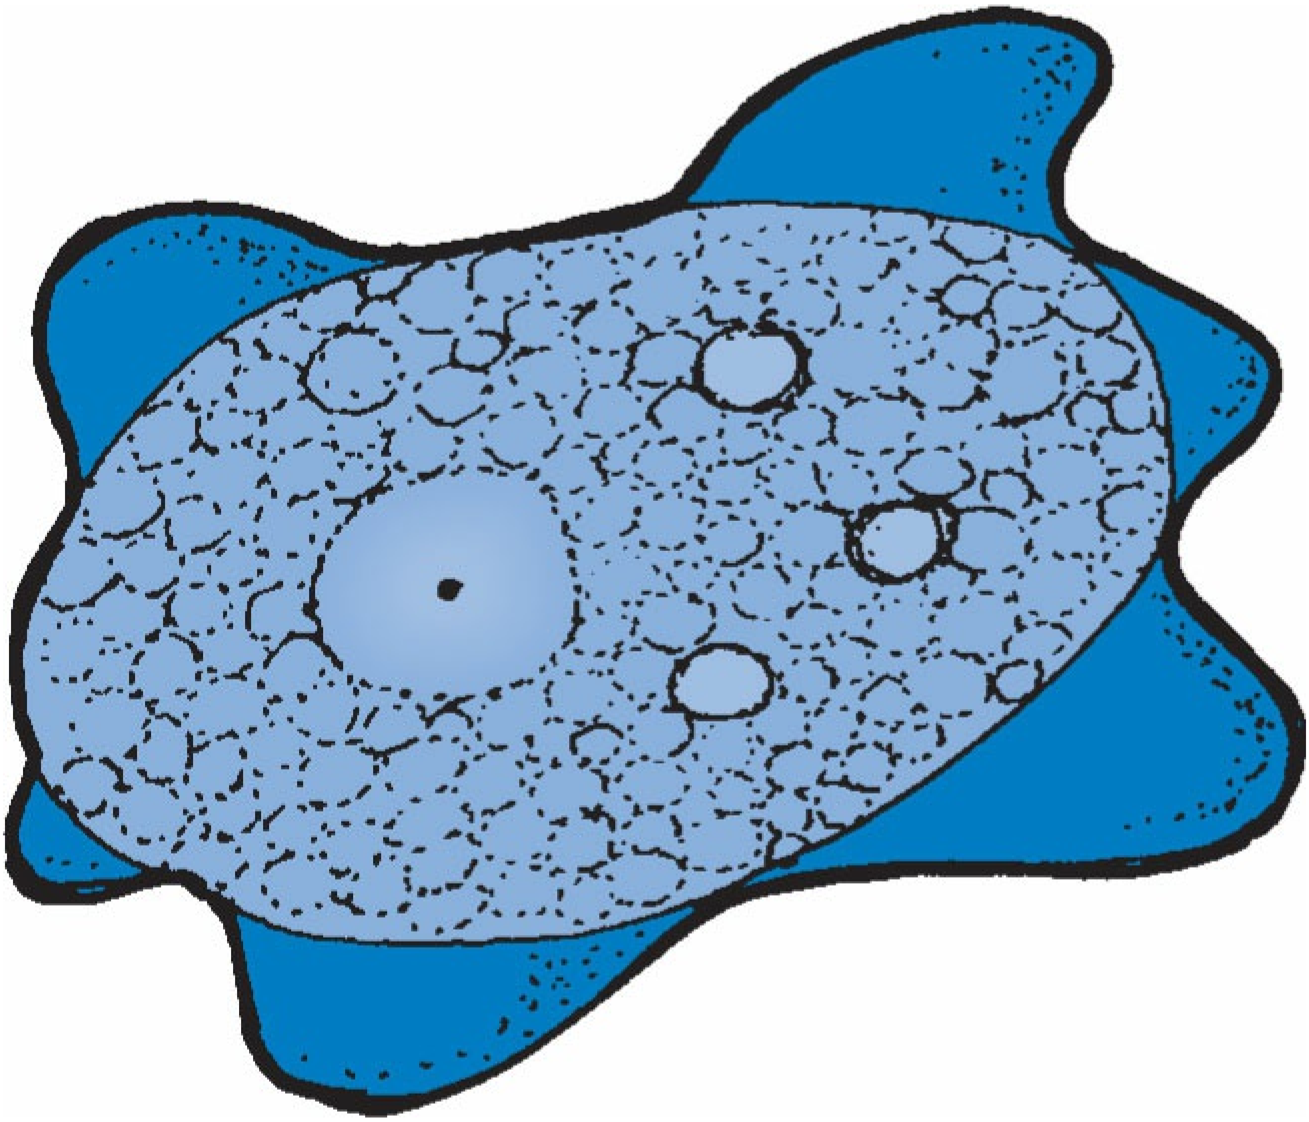

Figure 81-3 Entamoeba histolytica trophozoites.

Amebic Dysentery

DIAGNOSIS

CASE 81-4

QUESTION 1: B.W., a 39-year-old recent immigrant from rural India, presents to an urgent care clinic with a 14-day history of watery diarrhea with occasional blood, abdominal pain, and fever. On physical examination, he is a thin man complaining of abdominal discomfort and occasional nausea. His vital signs include blood pressure 150/90 mm Hg, heart rate 90 bpm, temperature 37.6°C. He has no signs of jaundice or lymphadenopathy. Examination is remarkable for slight abdominal distension and rebound tenderness in the right lower quadrant. Liver function tests are normal. Stool samples are collected and reveal stool positive for occult blood. Microscopic examination of stool for ova and parasites is ordered; light microscopy reveals trophozoites and cysts. Colonoscopy revealed flask-shaped intestinal mucosal ulcerations. A tissue biopsy of the ulceration showed trophozoites. Antigenic testing of stool samples confirmed presence of E. histolytica. What clinical findings does B.W. have that supports the diagnosis of amebic colitis?

Patients presenting with acute amebic colitis may present with bloody or watery diarrhea, abdominal pain, constipation, tenesmus, fever, rectal bleeding (especially in children), nausea, and anorexia.[36–39] On physical examination patients may present with elevated temperature, tachycardia, and hypertension in cases of severe colitis. Intestinal amebic dysentery may be suspected in patients from endemic areas with bloody or watery diarrhea, abdominal pain, and fever. Diarrhea lasting more than 10 days should be evaluated for intestinal parasites.[40] Almost all patients presenting with amebic colitis will have heme-positive stools. Microscopic examination of stool samples can only identify the presence of trophozoites or cysts but cannot differentiate between pathogenic or nonpathogenic strains of the Entamoeba species. Three stool samples from different days need to be collected, because cysts may be missed if only one sample is tested. Serology tests cannot determine between a current or past infection. There are various antigenic assay detection kits commercially available with varying specificity and sensitivity to differentiate the type of species found in the stool. B.W. is a recent immigrant from an endemic country and is presenting with symptoms consistent with amebic colitis. Antigenic examination of the stool confirmed B.W. has amebiasis, with the presence of E. histolytica.

CASE 81-4, QUESTION 2: What medications are available to treat B.W.'s symptomatic infection? What medication regimen is preferred?

Treatment is necessary if E. histolytica has been specifically identified. Treatment is not necessary with E. dispar infections.[36–38] Treatment involves the elimination of both trophozoites and cysts from the intestinal lumen. There are two classes of drugs to treat B.W.'s amebiasis: tissue amebicides and intraluminal amebicides. Those presenting with mild-to moderate intestinal symptoms or severe intestinal symptoms or extraintestinal disease should be treated with a tissue amebicide followed by a course of intraluminal amebicide therapy.[41] B.W.'s symptomatic amebic colitis needs to be treated with both a tissue amebicide and intraluminal agent. Tissue amebicides include nitroimidazoles, nitazoxanide (Alinia), and chloroquine. The drug of choice with a 90% cure rate are the 5-nitroimidazoles, metronidazole (Flagyl), and tinidazole (Tindamax).[29,39] Nitazoxanide shows promise, but the data are limited; chloroquine is ineffective in intestinal illnesses. Metronidazole will kill the trophozoites in the intestines and the tissues, but it does not eradicate the cysts from the intestine. To eradicate colonization, therapy should be followed with an intraluminal amebicide, such as paromomycin, diloxanide furoate (Furamide—not approved in the United States or Canada), or iodquinol (Yodoxin).

Table 81-3

Drug Therapy of Various Parasitic Infections[a]

Drug of Choice	Dosage	Adverse Effects	Warnings
Amebiasis			
Asymptomatic including cyst passers			
Luminal amebicides			
Paromomycin (drug of choice)	Adults and children: 25–35 mg/kg/day in three divided doses for 5–10 days	Nausea, vomiting, diarrhea, and cramps	Contraindicated in GI obstructions Use with caution in renal impairment
Iodoquinol	Adults: 650 mg PO TID × 20 days Children: 30–40 mg/kg/day PO TID × 20 days (max. 2 g/day)	Nausea, vomiting, and headache	Avoid use in elderly because of optic nerve damage
Diloxanide furoate (not available in the United States)	Adults: 500 mg PO TID × 10 days Children: 20 mg/kg/day in three divided doses × 10 days	Flatulence, nausea, and abdominal pain	
Symptomatic or invasive intestinal infections			
Tissue amebicides			
Metronidazole	Adults: 750 mg PO TID × 5–10 days Children: 35–50 mg/kg/day PO TID × 7–10 days	Nausea, headache, metallic taste, disulfiram reaction with alcohol, and abdominal discomfort	Avoid use in first trimester of pregnancy
Tinidazole	Adults: 2 g PO once daily × 3 days Children: 50 mg/kg (max. 2 g) × 3 days	Metallic or bitter taste, anorexia, nausea, vomiting, epigastric discomfort, and fatigue	Contraindicated in first trimester and those breast feeding
Followed by luminal amebicide: see above for dosing			

Amebic liver abscess			
Metronidazole	Adults: 750 mg PO/IV TID × 5–10 days Children: 35–50 mg/kg/day three divided doses × 5–10 days	Nausea, headache, metallic taste, disulfiram reaction with alcohol, and paresthesia	Avoid use in first trimester of pregnancy
Tinidazole	Adults: 2 g PO once daily × 3–5 days Children: 50 mg/kg (max. 2 g) × 5 days	Metallic or bitter taste, anorexia, nausea, vomiting, epigastric discomfort, and fatigue	Contraindicated in first trimester and those breast feeding
Followed by luminal amebicide agent to eliminate intestinal colonization—see above for dosing			
Ascariasis (Roundworm)			
Albendazole	Adults and children: 400 mg PO once	Nausea, vomiting, headache, and abnormal liver function tests	Avoid during pregnancy
Mebendazole (Withdrawn from market in the United States)	Adults and children: 100 mg BID PO × 3 days Or 500 mg PO single dose May repeat in 3 weeks if necessary	Headache, diarrhea, abdominal pain, and dizziness	Avoid during pregnancy Use with caution in hepatic disease and inflammatory bowel diseases
Enterobiasis (Pinworm)			
Mebendazole (withdrawn from market in the United States)	Adults and children: 100 mg PO once; repeat in 2 weeks	Diarrhea and abdominal pain	Avoid during pregnancy Use with caution in hepatic disease and inflammatory bowel diseases
Pyrantel pamoate	Adults and children: 11 mg/kg PO once (max. 1 g), repeat in 2 weeks	Nausea, vomiting, headache, dizziness, diarrhea, and abdominal cramps	Avoid in pregnancy Use with caution in hepatic disease
Albendazole	Adults and children: 400 mg PO once; repeat in 2 weeks	Nausea, vomiting, headache, and abnormal liver function tests	Avoid during pregnancy

Filariasis			
Diethylcarbamazine	Adults: Day 1, 50 mg PO; day 2, 50 mg TID; day 3, 100 mg TID; days 4–14, 6 mg/kg/day in three doses Children: Day 1, 25–50 mg; day 2, 25–50 mg TID; day 3, 50–100 mg TID; days 4–14, 6 mg/kg/day in three doses	Severe allergic or febrile reactions, gastrointestinal disturbance, and rarely encephalopathy	
Albendazole	400 mg PO once daily for	Nausea, vomiting,	Avoid during pregnancy

	10 days	headache, and abnormal liver function tests	
Flukes (Trematodes)[b]			
Praziquantel	Adults and children: 40 mg/kg PO 2 divided doses 4 hours apart (S. haematobium, S. mansoni, and S. intercalatum) 60 mg/kg PO in three divided doses 4 hours apart or two divided doses 6 hours apart (S. japonicum and S. mekongi)	Malaise, headache, dizziness, sedation, fever, and abdominal distress	Contraindicated with other strong CYP inducers (rifampin) Contraindicated in ocular cysticercosis
Giardiasis			
Metronidazole	Adults: 250 mg PO TID with meals × 5–7 days Children: 15 mg/kg/day PO TID × 5–7 days	Nausea, headache, metallic taste, and disulfiram reaction with alcohol	Avoid use in first trimester of pregnancy
Tinidazole	Adults: 2 g PO single dose Children: 50 mg/kg single dose	Metallic or bitter taste, anorexia, nausea, vomiting, epigastric discomfort, and fatigue	Contraindicated in first trimester and those breast feeding
Nitazoxanide	Adults and children: >12 years: 500 mg PO BID × 3 days Children: 7.5 mg/kg BID for 3 days in children <12 years old	Abdominal pain, diarrhea, vomiting, and headache	Use with caution in those with hepatic and renal impairment
Paromomycin (drug of choice in first trimester pregnancy)	Adults: 500 mg PO TID for 10 days Children: 25 mg/kg/day in three divided doses × 10 days	Nausea, vomiting, diarrhea, and cramps	Contraindicated in GI obstructions Use with caution in renal impairment
Albendazole	400 mg PO daily × 5 days	Nausea, vomiting, headache, and abnormal liver function tests	Avoid during pregnancy
Mebendazole	200 mg PO TID for 5 days	Headache, diarrhea, abdominal pain, dizziness	Avoid during pregnancy Use with caution in hepatic disease and inflammatory bowel diseases
Hookworm			
Mebendazole	Adults and children: 100 mg PO BID × 3 days OR 500 mg PO single dose	Headache, diarrhea, abdominal pain, and dizziness	Avoid during pregnancy Use with caution in hepatic disease and inflammatory bowel diseases
Albendazole	400 g PO single dose	Nausea, vomiting,	Avoid during pregnancy

		headache, and abnormal liver function tests	
Lice			
1% Permethrin (Nix)	See Table 81-4 for instructions	Occasional allergic reaction, mild stinging, and erythema	Use with caution in those sensitive to chrysanthemums Not recommended for eyebrow or eyelashes infestations
Ivermectin	Adults and children: 200 mcg/kg × 3, day 1, 2, and 10	Fever, pruritus, sore lymph nodes, headache, joint pains, and rarely hypotension	Use with caution in those with severe asthma

---

Leishmaniasis			
Sodium stibogluconate	Adults: 20 mg /kg IV or IM × 20–28 days Children: Same as adults	Gastrointestinal, malaise, headache arthralgias, myalgias, anemia, neutropenia, and thrombocytopenia; ECG abnormalities (ST- and T-wave changes)	Use with caution in those with cardiac disease Use with caution on those with real or hepatic impairment
Liposomal Amphotericin B	Immunocompetent: 3 mg/kg/day on days 1–5, 14, and 21. Repeat if need Immunocompromised: 4 mg/kg/day on days 1 through 5, 10, 17, 24, 31, and 38. Seek advice if further therapy is needed	Hypotension, chills, headache, anemia, thrombocytopenia, fever, and elevated serum creatinine	
Scabies			
5% Permethrin (Elimite cream)	Apply topically to whole body. Remove cream by washing (shower or bath) after 8–14 hours.	Rash, edema, and erythema	Use with caution in those sensitive to chrysanthemums
Alternatives for scabies			
Ivermectin	Adults: 200 mcg/kg PO; repeat in 2 weeks	Nausea, diarrhea, dizziness, vertigo, and pruritus	Use with caution in those with severe asthma
Lindane (Kwell)	Apply topically once	Not recommended in pregnant women, infants, and patients with massively excoriated skin Second-line therapy when other alternatives have failed.	Not recommended by American Academy of Pediatrics Second-line only Black box warning because of neurologic toxicity Banned in California,

			United Kingdom, Australia
Crotamiton 10% (Eurax)	Apply topically to whole body especially folds and creases. May repeat in 24 hours. Cleansing bath 48 hours after last application	Local skin irritation	Do not apply to raw, weeping skin. Not to be swallowed
Tapeworm[c,d]			
Praziquantel	Adults and children: 5–10 mg/kg PO single dose	Malaise, headache, dizziness, sedation, eosinophilia, and fever	Contraindicated with other strong CYP inducers (e.g., rifampin) Contraindicated in ocular cysticercosis
Hydatid cysts[e]			
Albendazole	Adults: 400 mg BID × 8–30 days, repeat if necessary Children: 15 mg/kg/day × 28 days, repeat if necessary (surgical resection may precede drug therapy)	Diarrhea, abdominal pain, rarely hepatotoxicity, and leukopenia	Avoid use during pregnancy
Trichomoniasis			
Metronidazole	Adults: 2 g PO × 1 day or 250 mg PO TID × 7 days Children: 15 mg/kg/day PO TID × 7 days	Nausea, headache, metallic taste, disulfiram reaction with alcohol, and paresthesia	Avoid use in first trimester of pregnancy

[a] Does not include drugs used in the treatment and prophylaxis of malaria. (See Table 81-1 for the drugs used for malaria prophylaxis, as well as guidelines by the CDC and WHO for treatment and prophylaxis of malaria.)

[b] Schistosoma haematobium, Schistosoma mansoni, Schistosoma japonicum, Clonorchis sinensis, and Paragonimus westermani.

[c] Off-label use for tapeworms. Dose for Hymenolepis nana is 25 mg/kg single dose.

[d] Diphyllobothrium latum alternative treatment: adults, niclosamide 2 g orally once; children, 50 mg/kg (max. 2 g) orally once.

[e] Echinococcus granulosus and Echinococcus multilocularis.

BID, twice daily; IM, intramuscularly; IV, intravenously; PO, orally; TID, three times daily.

Source: Drug Facts and Comparisons. https://fco-factsandcomparisons-com.ezproxymcp.flo.org/action/home?siteid=5&reauth. St. Louis, MO: Wolters Kluwer Health, Inc. Accessed July 31, 2017.

B.W.'s amebic colitis should be treated with metronidazole 750 mg orally or IV 3 times a day for 5 to 10 days.[34] Alternative treatment with tinidazole 2 g once daily for 3 days is often better tolerated because of its shorter duration of therapy. Common adverse effects of metronidazole are nausea, metallic taste, and abdominal discomfort. Patients should be warned of a possible disulfiram reaction with alcohol consumption during and up to 72 hours after the completion of therapy.[42] This should be followed by an intraluminal amebicide; the drug of choice is paromomycin 25 to 35 mg/kg/day orally in three divided doses for 5 to 10 days, second-line agents include diloxanide or iodoquinol[28] (see Table 81-3). The most common adverse effects of paromomycin are abdominal pain/cramping, nausea, and diarrhea. Paromomycin and metronidazole should not be taken simultaneously.

In those with a confirmed diagnosis of amebiasis, one study showed the addition of the probiotic Saccharomyces boulardii with metronidazole reduced the duration of bloody diarrhea and aided in the clearance of cysts when compared to metronidazole alone.[43]

B.W. must be monitored for the improvement of symptoms of diarrhea and abdominal pain. Follow-up should continue for 3 months after treatment. Three separate stool samples should be examined for cysts.[44]

Amebic Cyst Carrier

CASE 81-5

QUESTION 1: M.A., a 56-year-old man, presents to his PCP for a routine examination after multiple mission trips to Southeast Asia. M.A. is currently asymptotic, but his stool tested positive for E. histolytica cysts. Should M.A. be treated?

M.A. is an asymptomatic cyst passer. Cyst passers often do not develop invasive infections and sometimes can clear the infection spontaneously.[29] Detection of the nonpathogenic cyst E. dispar does not require treatment, but all asymptomatic patients with positive test results of E. histolytica must be treated to reduce the transmission to others.[28,29]

CASE 81-5, QUESTION 2: What medications should be used to treat M.A.?

Intraluminal amebicides are the drug of choice in the treatment of asymptomatic amebiasis. Paromomycin is the drug of choice, 25 to 35 mg/kg/day in three divided doses for 5 to 10 days with meals. Diloxanide furoate (not commercially available in the United States) or iodoquinol may also be recommended, but paromomycin has a higher efficacy rate when compared to diloxanide.[45] M.A.'s stools must be tested monthly for 3 months to assure eradication of the infection.[44]

Extraintestinal Infections

CASE 81-6

QUESTION 1: M.M. is a 26-year-old man presenting to the ED complaining of upper right quadrant abdominal pain, fever, and chills. Upon physical examination the patient shows signs of difficulty breathing during inspiration with pain radiating to the shoulder and back and abdominal tenderness. Rales at the right base could be heard on examination. Laboratory results are significant for leukocytosis with neutrophilia, mild anemia, elevated alkaline phosphate, and alanine aminotransferase. Blood serology shows high antibody titers for Entamoeba. Computed tomography (CT) confirmed presence of an abscess in the right lobe of the liver. How should M.M. be managed?

Extraintestinal infections occur in less than 1%, of which liver abscesses are the most common. The right hepatic lobe is the most frequently affected area because of the portal circulatory system of the colon.[38] M.M.'s clinical presentation and laboratory findings are consistent of a hepatic abscess. Only diarrhea is reported in approximately 50% of those infected.[38] The drug of choice for amebic liver abscess is metronidazole for 5 to 10 days followed with a luminal agent such as paromomycin.[37] Aspiration or drainage of the abscess is not recommended unless there is a failure to respond to therapy after 4 to 5 days, evidence of a secondary infection or impending rupture into the pericardium. After the completion of therapy, M.M. should be monitored for regression of the abscess with ultrasounds, and lesions may take up to 12 months to resolve. Complications of hepatic abscesses may include perforation of the abdominal cavity, septic shock, or superinfections. Infections outside of the intestines or liver are extremely rare (<0.1%), dissemination of the amebae to the brain or skin are almost always associated with amebic liver abscess. Because of the rarity of these infections, there are no definitive guidelines for treatment.[36,37]

Treatment During Pregnancy

CASE 81-7

QUESTION 1: S.W., a 26-year-old woman refugee from Sudan, presents to the clinic with an 8-day history of watery stools with blood streaks, abdominal cramping, and a fever. She is currently 12 weeks pregnant and has received no prenatal care prior to her arrival in the United States 4 weeks ago. Physical examination reveals a temperature of 38°C, HR 80 bpm, and blood pressure 140/85. An examination of fresh stools is positive for occult blood and trophozoites. Antigenic testing confirmed the presence of E. histolytica. Bacteria cultures are negative for Campylobacter, salmonellosis, and shigellosis. Ultrasound imaging and computed tomography (CT) are negative for the presence of liver abscesses. A diagnosis of intestinal amebiasis is made.

How would you manage S.W.'s infection? What are your concerns regarding her current condition?

S.W. needs to be treated for her intestinal amebiasis. The treatment of choice is metronidazole, but she is in her first trimester of pregnancy. Nitroimidazoles such as metronidazole and tinidazole should be avoided during the first trimester of pregnancy. Metronidazole readily crosses the placenta, and effects on the development of the fetus are unknown.[42] S.W. should be treated with paromomycin 25 to 35 mg/kg/day in three divided doses for 5 to 10 days. Paromomycin is an aminoglycoside that is poorly absorbed in the bowel with an excellent safety profile. The most common adverse effects are nausea, vomiting, and abdominal cramps. S.W.'s stools must be examined for 3 months to assure resolution of the infection.[36,37]

If S.W.'s infection does not resolve or progresses to fulminant colitis or amebic liver abscess, she will safely be beyond her first trimester and should be treated appropriately with a tissue amebicide such as metronidazole followed by a luminal agent such

---

as paromomycin, or second-line agents such as iodoquinol or diloxamide furoate. If iodoquinol is chosen, the most common adverse effects are headache, nausea, and vomiting. Optic nerve damage is a concern with elderly patients and should be avoided. Reported cases of peripheral neuropathy have occurred in doses in excess of the recommended dose. Should diloxamide furoate be prescribed the most common adverse effect is flatulence, but it is not commercially available in the United States.[36]

GIARDIASIS

Prevalence and Transmission

Giardia is a globally endemic illness caused by the protozoa Giardia lamblia.[46] The highest number of cases are typically seen in developing countries with inadequate sanitary conditions, untreated water, or contaminated food. Although primarily seen in Asia, Africa, or South America, it is the most frequent parasitic intestinal disease in the United States.[34,47] Those at greatest risk live in rural areas with poor sanitation, low socioeconomic conditions, and have contact with infected individuals or travel internationally. Giardia is most prevalent in children and immunocompromised individuals. Presentation of illness varies between individuals from self-limiting diarrhea to more severe symptoms of chronic diarrhea, abdominal cramps, loose pale greasy stools that float, fatigue, weight loss and malabsorption of fat, lactose, vitamins A and B_{12}, but many present with no symptoms.[48] Severe Giardia infections may lead to mucosal damage in the small intestines.

Life Cycle

Infection occurs with the ingestion of cysts in contaminated water, food, or by the fecal–oral route. In the small intestine, excystation releases trophozoites (each cyst produces two trophozoites).[46] Trophozoites replicate in the lumen of the proximal small bowel where they can be free or attached to the mucosa by a ventral sucking disk. Encystation occurs as the parasites transit toward the colon and are excreted in the feces. The cysts are hardy, surviving in environmental elements such as cold water and chlorination for weeks (Fig. 81-4).[47,49]

Diagnosis

SIGNS AND SYMPTOMS

CASE 81-8

QUESTION 1: P.C., a 23-year-old woman who returned 1 week ago from a mission trip from Zambia, presents to the clinic with complaints of diarrhea, pale-colored foul-smelling greasy stools, abdominal cramps, and fatigue. She states she has been having diarrhea with occasional constipation for about 2 months. She experienced other bouts of diarrhea while on her year-long mission, but it resolved itself quickly, and symptoms occurred typically after swimming in the lake. She has lost 17 pounds since the diarrhea started. She denies any blood or mucous in her stool and has no complaints of fever. Laboratory findings are the following: Fecal fat content >12 g (normal 7 g), complete blood counts (CBC) results are anemia with thrombocytopenia and low levels of vitamin B_{12}. Three separate stool sample were positive for G. lamblia cysts with antigenic tests confirming the presence of G. lamblia.

What clinical findings does P.C. have that support the diagnosis of Giardia?

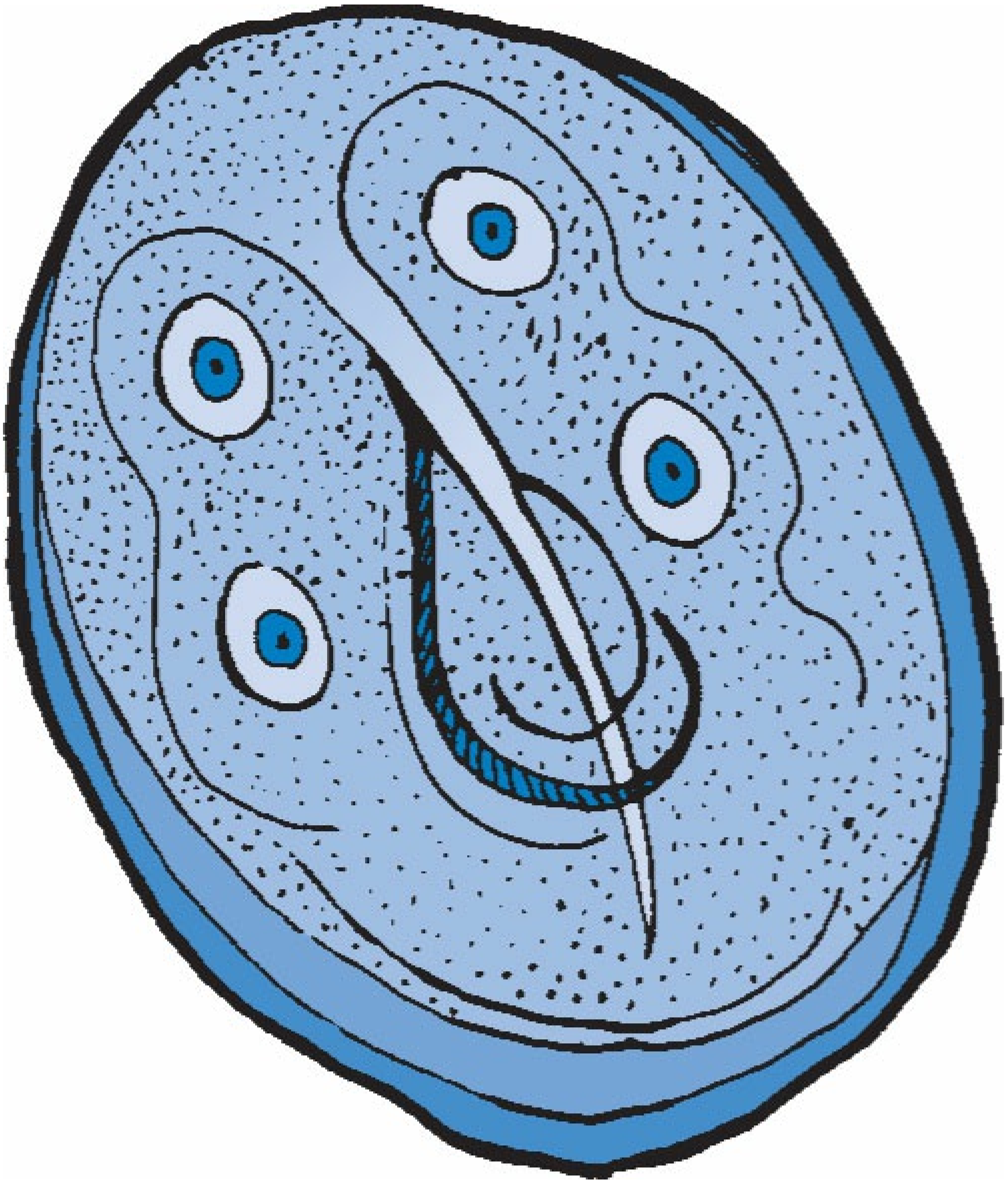

Figure 81-4 Giardia lamblia cyst.

Patients with Giardia may be asymptomatic, present with self-limiting diarrhea or with symptoms of chronic diarrhea with abdominal pain, yellowish greasy foul-smelling stools, abdominal distention, weight loss, or flatulence. Patients presenting with chronic diarrhea may suffer from dehydration and malabsorption of fat, lactose, and vitamins A and B_{12}.[47,50] The typical incubation period is 6 to 15 days after ingestion of the cysts. Infections may occur with as little as 10 cysts.[51] Confirmation of a giardiasis diagnosis is confirmed by signs and symptoms and the presence of cysts or trophozoites in stool samples. One stool sample may miss the presence of cysts, so it is recommended to test multiple stool samples (at least three). Antigenic testing of stool samples either ELISA or direct fluorescent antigen tests are more sensitive than traditional wet mount microscopy and should be performed if a patient presents with symptoms consistent with giardia but have multiple negative results for cysts. A differential diagnosis ruling out bacterial (Salmonella, Shigella, Campylobacter) and viral (rotavirus, norovirus) causes should be made because the presentation may be similar. Giardia differs from these infections by its length of illness (7–10 days before first presentation) and evidence of weight loss.[49]

P.C.'s history of missionary work in Zambia is considered high risk. She may have consumed contaminated food or water, particularly if she swallowed lake water. Her symptoms are consistent with chronic giardia: foul-smelling greasy stools, periods of diarrhea and constipation, fatigue, and abdominal cramps. Some patients will present with flatulence as well. Her laboratory results are consistent with malabsorption: fecal fat content is greater than 12 g (normal fecal fat content is <7 g)[50]; results greater than 7 is indicative of fat malabsorption resulting in steatorrhea.[52] Chronic infections may also present with anemia and low vitamin B_{12} levels. P.C. had G. lamblia cysts identified in the stool after three tests and confirmed with antigenic testing. A definitive diagnosis of Giardia can be made.

CASE 81-8, QUESTION 2: How should P.C. be treated?

Treatment of choice for P.C.'s giardiasis is a nitroimidazole. Metronidazole 250 mg orally 3 times a day for 5 to 7 days is the preferred option with efficacy rates from 52% to 100%.[53] Tinidazole 2 g as a single dose may be better tolerated because of the shorter duration of therapy with similar rate of efficacy. Alternative treatment options include nitazoxanide (Alinia) 500 mg orally twice a day for 3 days, paromomycin 500 mg 3 times daily for 10 days (drug of choice during the first trimester of pregnancy), albendazole (Albenza) 400 mg orally once daily for 5 days. Quinacrine[54] and furazolidone[55] are effective options but are not commercially available in the United States.

P.C. should be counseled to practice good hygiene, washing hands with soap and water for at least 20 seconds, to control transmission of disease.[56] Symptoms of diarrhea typically subside in 1 to 2 days and completely resolve in 10 days. Symptoms of malabsorption may take up to 4 to 8 weeks.[53,57–60] If treatment failure occurs, another course of therapy is necessary. Resistant strains have been treated with success with either higher doses or a longer course of therapy.[49]

ENTEROBIASIS

Prevalence

Human enterobiasis or pinworm infection is caused by the intestinal nematode, Enterobius vermicularis. It is the most common helminthic infection worldwide. The highest rate of infection occurs in school-aged children (5–10 years), institutionalized persons, and household members or caretakers of an infected individual. Unlike other helminth infections, all socioeconomic groups are affected. Transmission occurs via the fecal–oral route with finger sucking considered a source of infection for children. If one family member is infected, all members of the family must be treated.[61–63]

Life Cycle

Humans are the only host of E. vermicularis. The entire life cycle occurs in the gastrointestinal system for approximately 4 weeks. Infected eggs are ingested from contaminated hands that have scratched the perianal area, food, or water. Person-to-person transmission may occur from contaminated clothing or bed linens. Once eggs are ingested they hatch in the small intestine (duodenum), larvae migrates to the large intestine where they molt twice before becoming adult worms. Copulation occurs in the ileum, where the male typically dies and passes in the stool. The gravid female settles into the large intestine and caecum. The female body fills with approximately 11,000 eggs and makes nocturnal migrations to the rectum and anus where oxygen is needed for the maturation of eggs. Eggs are then deposited in the area around the anus causing severe pruritus.[64,65]

SIGNS AND SYMPTOMS

CASE 81-9

QUESTION 1: N.D. is a 5-year-old boy presenting to the pediatrician. N.D.'s mother states he has been scratching the perianal area for several days. The intense itching has been keeping him up at night and he is irritable during the day. N.D. is 3 feet 9 inches and weighs 19 kg. A cellophane tape swab is placed over the skin of the perianal area, evidence of E. vermicularis eggs are found under the microscope.

What signs and symptoms does N.D. exhibit to confirm a diagnosis of pinworm?

Many infected with pinworms are asymptomatic or present with mild symptoms; the most common symptom being nocturnal perianal pruritus and scratching because of the deposit of eggs to the perianal skin. The intense scratching may lead to secondary bacterial infections and sleep disturbances. Patients with major infestations may present with abdominal pain, anorexia, or insomnia. Enterobiasis infections rarely cause serious disease, but it may result in dysuria, appendicitis, or vaginal infections.[66,67]

N.D. is presenting with perianal itching, inability to sleep because of intense itching and a positive "tape test" showing E. vermicularis eggs indicative of a pinworm infestation.

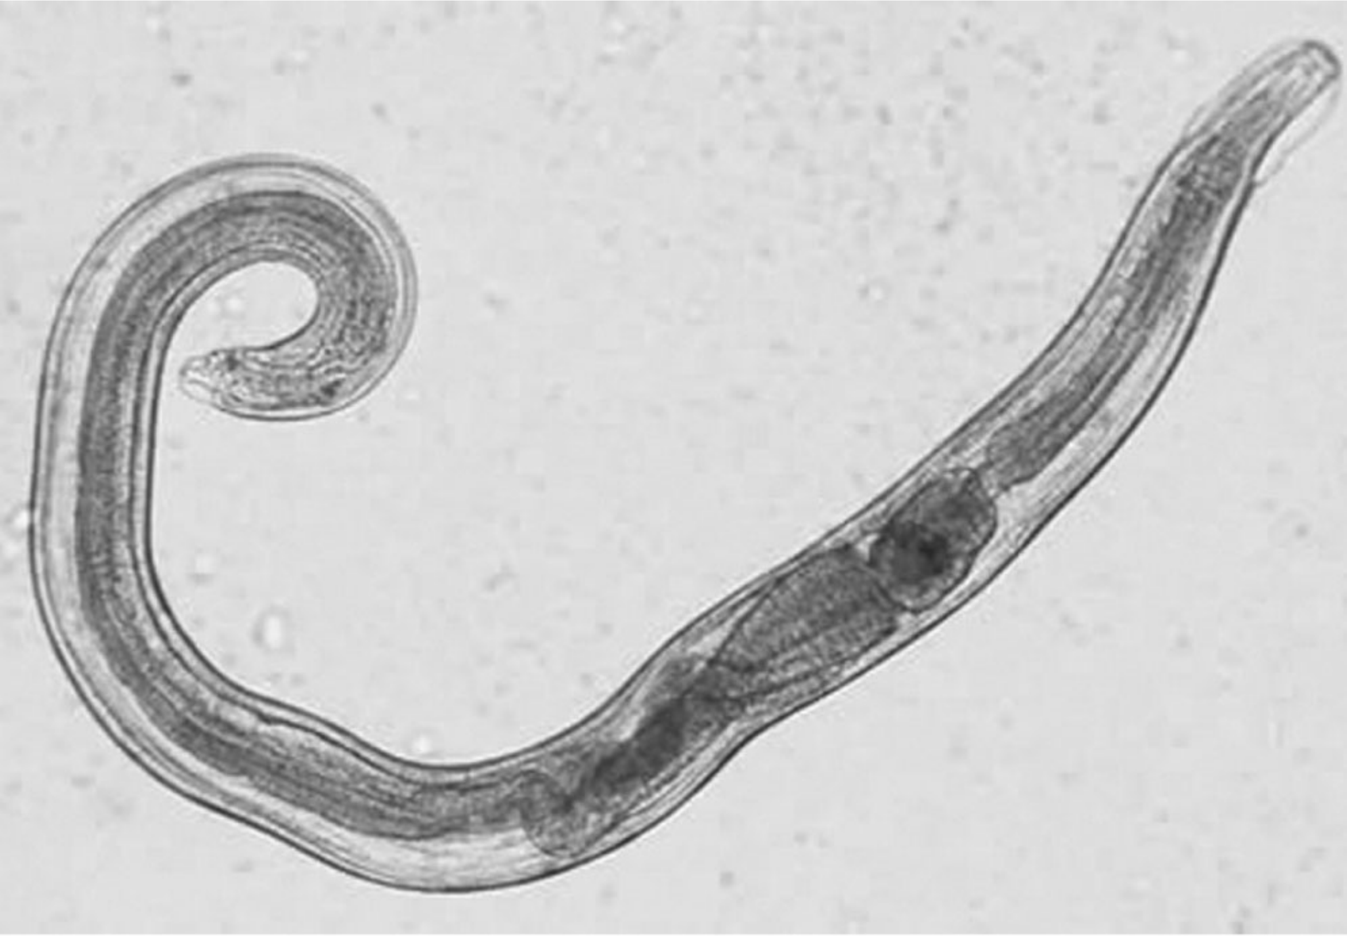

Figure 81-5 Adult male Enterobius vermicularis image. Centers for Disease Control and Prevention (CDC)-DpDx-Laboratory Identification of Parasitic Diseases of Public Concern. Enterobiasis Image Gallery. https://www.cdc.gov/dpdx/enterobiasis/index.html. Accessed July 31, 2017.

CASE 81-9, QUESTION 2: How should N.D.'s infection be managed? Should his parents be treated?

There are three options for the treatment of pinworm: albendazole (Albenza), pyrantel pamoate (PinX—available without a prescription), and mebendazole (not commercially available in the United States). Albendazole 400 mg as a single dose or pyrantael pamoate 11 mg/kg (maximum 1 g) are viable options for N.D.; a second dose must be repeated in 2 weeks. Mebendazole is currently not commercially available in the United States, but it is available internationally. Mebendazole is given as a single 100 mg dose and repeated in 2 weeks.

Albendazole and mebendazole are broad-spectrum antihelmites that selectively interferes with the microtubules in the intestinal cells of nematodes and glycogen depletion leading to their death.[68,69] Albendazole is considered the drug of choice in the treatment of enterobiasis with a 90% cure rate. Both albendazole and mebendazole are well tolerated with abdominal pain as the most common adverse effect reported. Pyrantel pamoate is a depolarizing neuromuscular agent that acts by paralyzing adult worms, resulting in their expulsion in the stool before eggs are laid.[69] The most common adverse effects are nausea and vomiting. The liquid formulation must be shaken well before use and may be mixed with fruit juice or milk.

All members of N.D.'s family needs to be treated simultaneously. Other preventative methods include proper hand hygiene, particularly after toilet use and before meals, trimming of fingernails, and frequent washing of bed linens and undergarments using hot water.[66]

CESTODIASIS

Description

Intestinal cestodes (tapeworms) are segmented worms; adults primarily live in the gastrointestinal tract, but larvae can live in any organ.[70] There are several species that affect humans: Taenia saginata (beef tapeworm), Taenia solium (pork tapeworm), Diphyllobothrium latum (broad or fish tapeworm), Taenia asiatica (Asian tapeworm), and Hymenolepis nana (dwarf tapeworm). Humans become infected by eating raw or undercooked meat (pork or beef) or fish (Diphyllobothrium latum).[71]

A tapeworm attaches to the mucosa of the intestines by a scolex, the anterior portion of the tapeworm "head of the tapeworm."[70–72] The crown of the scolex is referred to as the rostellum; it may be armed with hooklets or unarmed (no hooklets). Proglottids or segments form behind a short neck. As each proglottid matures, they form a chain called a strobili, giving the tapeworm its ribbon-like appearance. The length of the strobili varies by species (T. saginata may have over 2,000 proglottids). Mature proglottids contain eggs that are indistinguishable between species. A definitive diagnosis is made by examining the scolex, proglottids, and eggs.

Tapeworms obtain nutrients through their skin directly from the host, they do not invade the tissue mucosa or acquire blood; therefore, symptoms are often absent or mild in nature.[71] Typical symptoms involve the gastrointestinal tract, mild eosinophilia, and elevated IgE levels may be detected. T. solium infections may lead to cysticercosis; neurocysticercosis, the most serious form, involves the central nervous system. It is important, therefore, to seek treatment with any tapeworm infection.

Life Cycle

Humans are the only definitive host for T. saginata and T. solium. Cattle or pigs are infected by ingesting vegetation contaminated with eggs or gravid proglottids passed in feces. Eggs hatch and invade the intestinal wall and migrate to the muscles where they develop into cysticerci. Humans become infected by eating raw or undercooked meat. In humans, the cysticercus develop in the small intestines to an adult worm over a period of 2 months and can survive for years. Adult worms produce proglottids, which mature and become gravid, detach from the worm, and migrate to the anus or are passed in feces.[73]

Epidemiology

It is estimated that the prevalence of Taenia infections is approximately 170 to 200 million cases worldwide.[71] T. solium occurs worldwide where pigs are raised, but it is most prevalent in Latin America, sub-Saharan Africa, China, India, and Southeast Asia.[70–71] T. saginata can occur anywhere raw or undercooked beef is eaten. Most prevalent areas of occurrence are Eastern Europe, Russia, East Africa, Latin America, Indonesia, and China.[73] Rural and poor socioeconomic areas in developing countries with poor hygiene are at greatest risk.[74] Most cases of neurocysticercosis in industrial countries are primarily seen in refugees, immigrant populations, or travelers from endemic countries.

Cysticercosis

Cysticercosis is caused by the larval cysts of the T. solium tapeworm. The larvae migrate to muscle tissue, brain, subcutaneous tissue, or the eye. When the infection develops in the central nervous system it is called neurocysticercosis and is responsible for one-third of acquired epilepsy cases worldwide.[75] Signs and symptoms vary by location of the cyst. Clinical manifestations of cysts in the muscle may be absent other than a lump under the skin. Cysts that deposit in the eye may cause floaters in the eye or blurry vision.[76] Clinical manifestations of neurocysticercosis depends on how many cysts are found and the location; symptoms include seizures, focal neurologic deficits, cognitive decline, and increased intracranial pressure.[76,77]

Diagnosis of neurocysticercosis is made by clinical presentation and radiologic imaging such as magnetic resonance imaging (MRI) or CT scans.[74] Treatment should be customized for each patient, depending on the size, location, and stage of the cysticerci. Treatment includes use of antihelminthic agents, such as praziquantel and/or albendazole. Coadministration of corticosteroids and antiepileptic drugs are often used to manage seizures and the inflammatory response because of the cysticidal activity of praziquantel therapy. Severe cases may require surgery.[77–80]

Taenia Saginata and Taenia Solium

SIGNS AND SYMPTOMS

CASE 81-10

QUESTION 1: L.D. is a 28-year-old missionary who lived 12 months in Ethiopia. He has returned to the United States with complaints of perianal itching and diffuse abdominal discomfort (primarily cramping). He reports no fever, mild diarrhea, and states that he sees “moving pieces of rice-looking objects” in his stool. Laboratory tests show slightly elevated eosinophil count and IgE levels. Three stool samples, obtained on separate days, and a cellophane tape test of the perianal area revealed presence of T. saginata.

Are L.D.’s symptoms consistent with Taenia infection? How can infections be differentiated?

Patients presenting with tapeworm infections may present with a range of symptoms. Many present with no symptoms, but if symptoms are present then they are often mild. Symptoms include abdominal pain, cramps, flatulence, constipation, nausea, vomiting, headache, vitamin deficiency, or weight loss. More severe symptoms include appendicitis and pancreatitis. Patients may report the voiding of segments from the anus and in the feces. Some patients may present with moderate eosinophilia and elevated IgE because of the weak immunogenic activity of the adult worms.[72]

The eggs of T. saginata and T. solium are morphologically indistinguishable. A definitive diagnosis of species can be made by examining the scolex (in rare cases) or more likely mature gravid proglottids. Eggs and proglottids are only detected in the feces 2 to 3 months after the infection has been established. The CDC recommends three separate stool samples on different days to establish a diagnosis. T. solium scolex is characterized by a scolex with four large suckers and rostellum with two rows of hooks (see Fig. 81-6).[72,81,82] T. saginata has a scolex with four suckers but no rostellum or hooks (see Fig. 81-7).[81] Biomolecular assays are more accurate than microscopic stool examinations to distinguish between species but are only available in a research laboratory setting.[82]

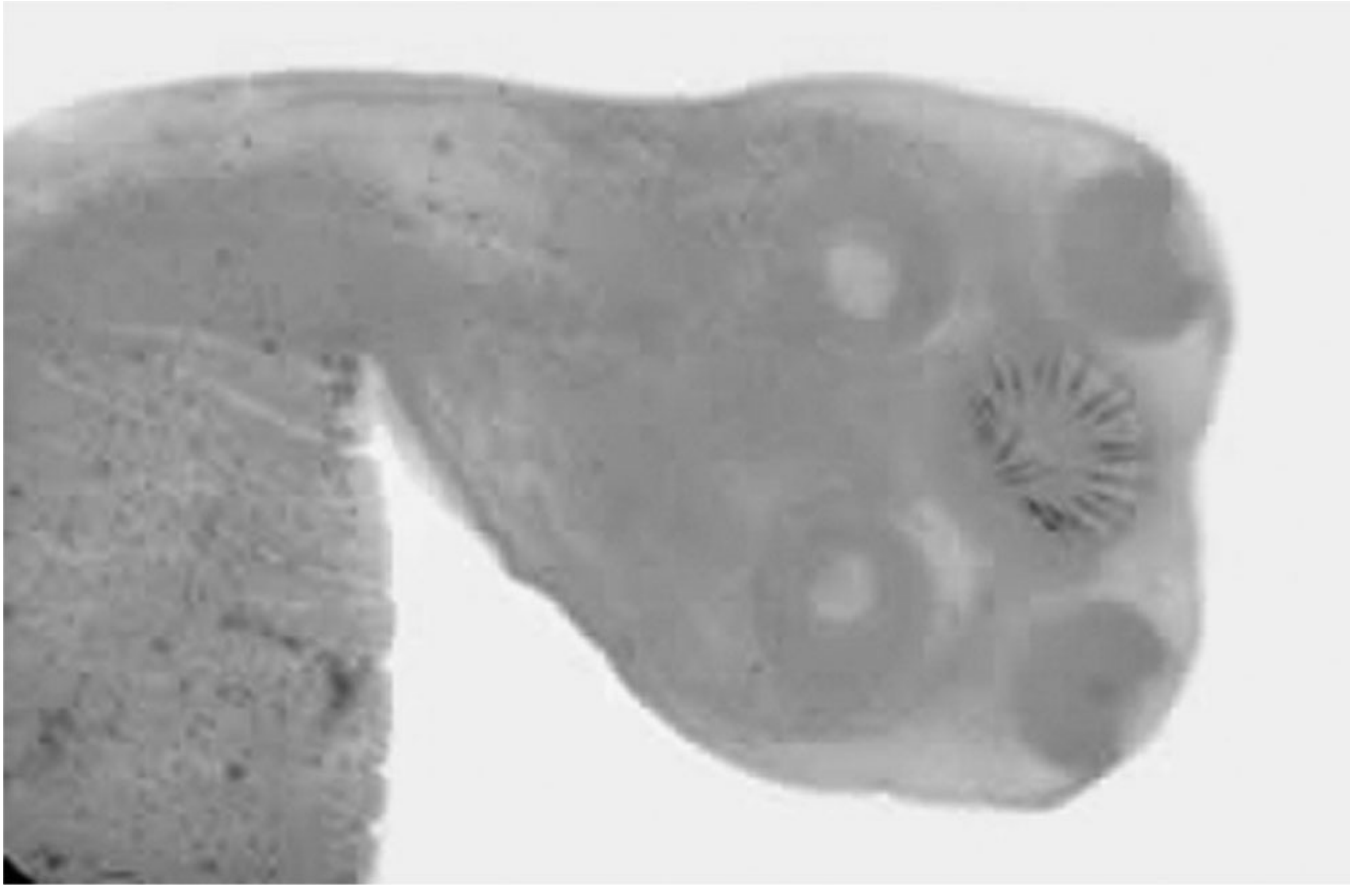

Figure 81-6 Scolex of T. solium image. (Source: Centers for Disease Control and Prevention (CDC)-DpDx-Laboratory Identification of Parasitic Diseases of Public Concern. Taeniasis Image Gallery. https://www.cdc.gov/dpdx/taeniasis/index.html. Accessed July 31, 2017.)

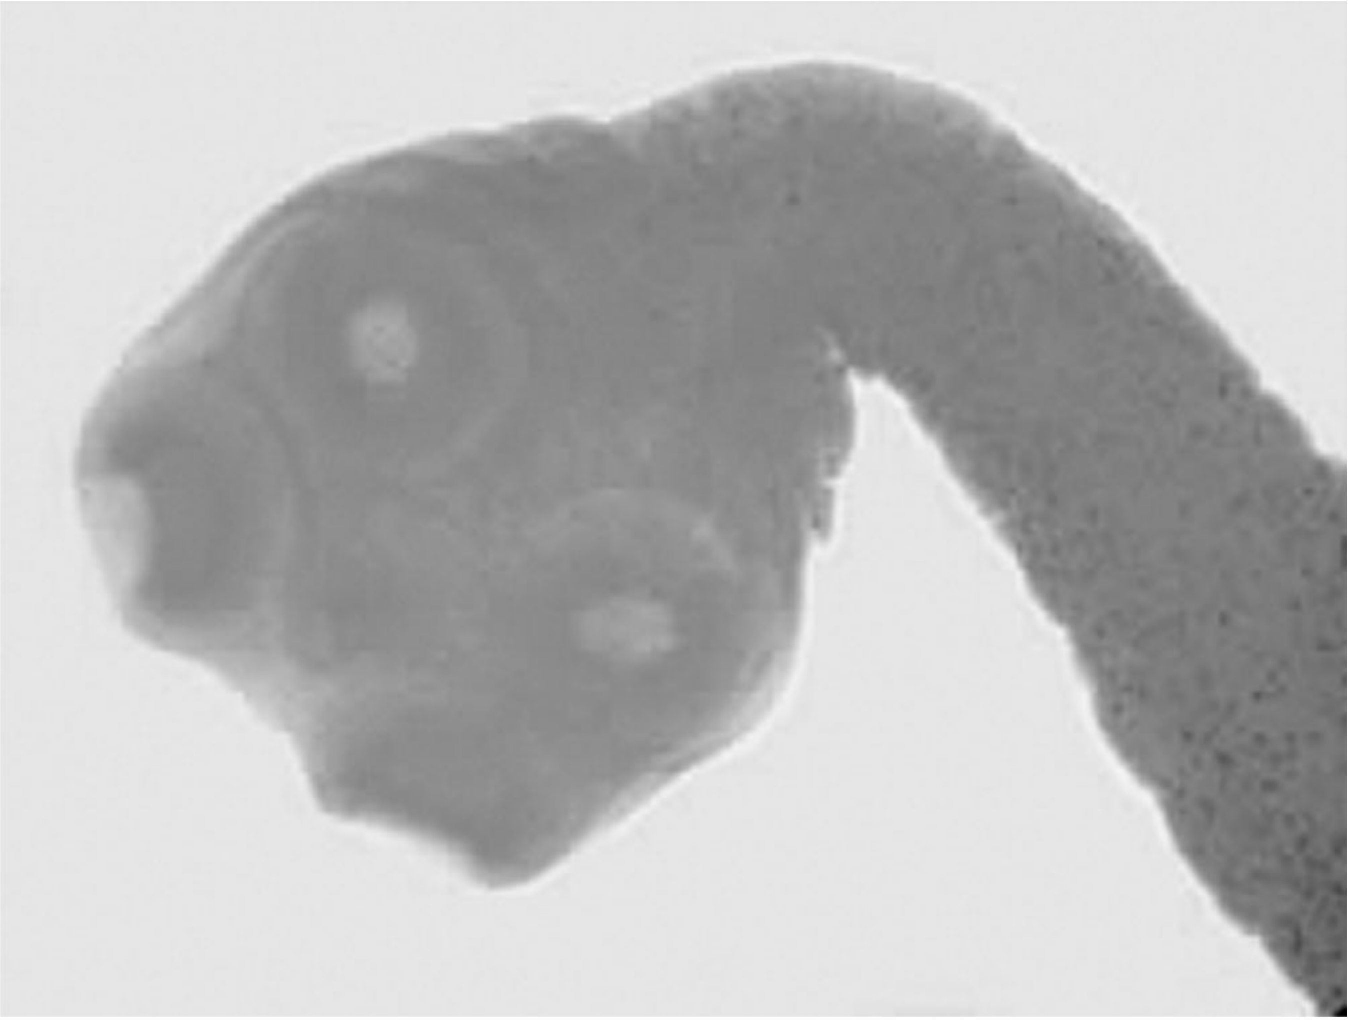

Figure 81-7 Scolex of T. saginata image. (Source: Centers for Disease Control and Prevention (CDC)-DpDx-Laboratory Identification of Parasitic Diseases of Public Concern. Taeniasis Image Gallery. https://www.cdc.gov/dpdx/taeniasis/index.html. Accessed July 31, 2017.)

CASE 81-10, QUESTION 2: How should L.D. be treated and how should it be evaluated?

The drug of choice for both T. saginata and T. solium infections is praziquantel (Biltricide) 5 to 10 mg/kg as a single dose.[83] Praziquantel works by killing the adult worm but does not destroy the eggs. Typical adverse effects include malaise, headache, dizziness, abdominal discomfort, and rarely urticaria. L.D. should be advised to swallow the tablet whole with water and a meal. The bitter taste of the tablet may cause L.D. to gag or vomit, so it is advisable to swallow the tablet promptly. Praziquantel cannot be chewed, but it may be halved or quartered. It is contraindicated to administer praziquantel with strong Cytochrome P450 (CYP450) inducers, such as rifampin, since adequate blood levels of praziquantel may not be achieved. L.D. should also be advised to not drive or operate heavy machinery on the day of treatment and the following day. Praziquantel has a high cure rate (up to 98%) in T. saginata and T. solium infections.[84]

An alternative regimen is niclosamide 2 g as a single oral dose for adults and 50 mg/kg in children. It is not available for human use in the United States. For those infections resistant to praziquantel and niclosamide, nitazoxanide has been used with success in T. saginata infections.[71] With any treatment it is recommended to examine stool samples for eggs 1 and 3 months after treatment to confirm eradication of the infection.

Recovery of the scolex for species identification may be necessary; purging of the bowel is recommended.[71] There are two options: administer electrolyte–polyethylene glycol prior to therapy or administer castor oil or magnesium sulfate solution within 2 hours of taking the anthelminthic drug. The tapeworm and its fragments should pass within 6 to 12 hours. Patients should be instructed to collect all feces for up to 72 hours to collect all fragments.

PEDICULOSIS

Prevalence

Pediculosis (lice infections) can be caused by Pediculus humanus capitis (head lice) (Fig. 81-8) , Pediculus humanus (body lice), or Pthirus pubis (crab lice). Lice infections remain a major problem throughout the world, and infestations can be present in all socioeconomic groups.[85] It is estimated that treatment costs for head lice may exceed $1 billion in the Unites States.[86]

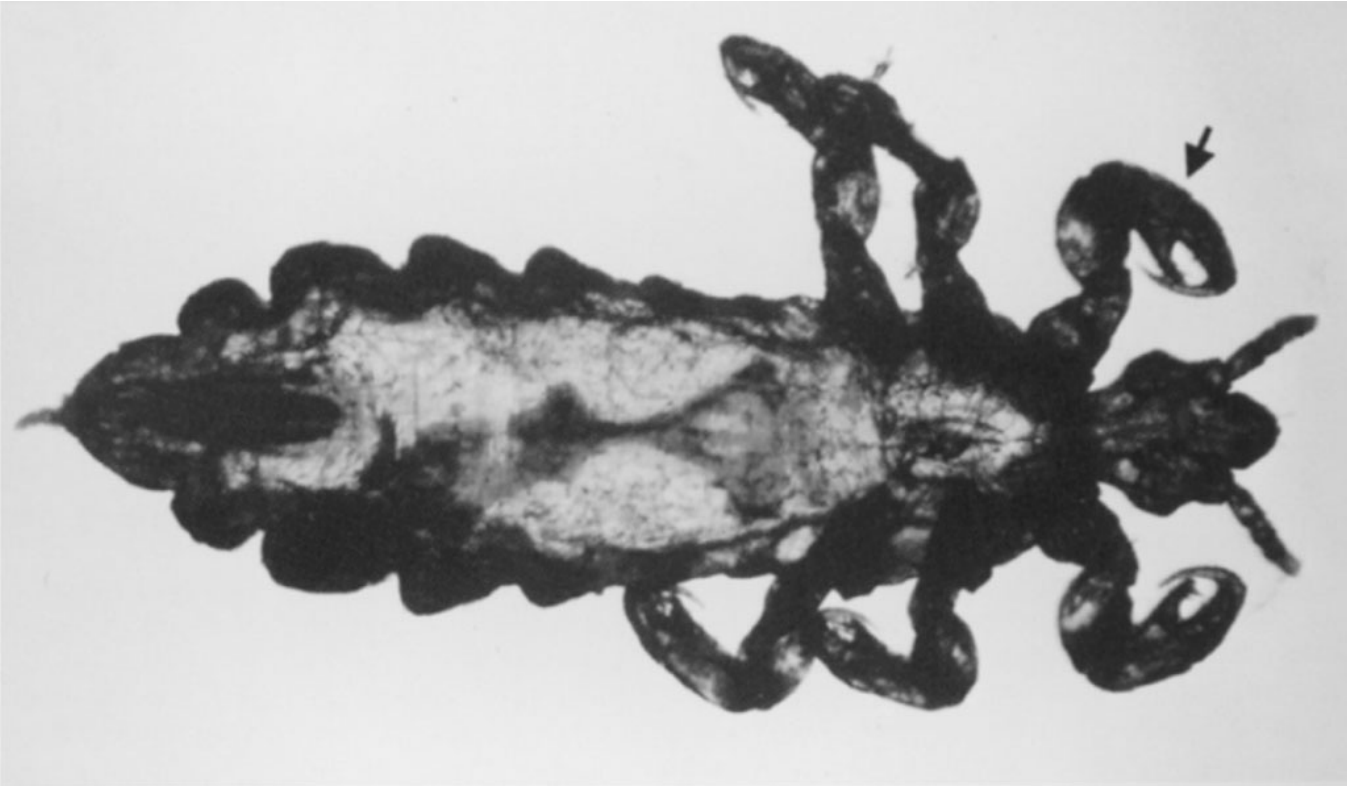

Figure 81-8 Pediculus humanus capitis (head lice).

Life Cycle

Head and body lice have similar life cycles, but their habitat preferences distinguish the two varieties. The life cycle of lice has three stages: egg, nymph, and adult. After fertilization, the female lays eggs (up to 10 a day), which attaches tightly to hair or seams of clothing. The eggs (nits) (see Fig. 81-9) hatch in 7 to 10 days and produce nymphs, which go through three molts to become adults. Louse feed by injecting a small amount of their saliva into the host and withdraw small amounts of blood; without these meals the louse will die. The lice penetrate the host skin via stylets within their head and attach themselves by a circlet of teeth on their proboscis. Crab lice are usually found in pubic hair, less frequently on facial hair, eyebrows, eyelashes, and axillary hairs.[85,87–89]

Epidemiology

The highest incidence of head lice is seen among schoolchildren aged 3 to 12 years and in household members. It is less common in African Americans because of different hair texture. The incidence of head lice infestation in the United States has been estimated to be as much as 12 million cases.[90] Body lice infest clothing by laying their eggs on the fabric. Head and crab lice infest hair by laying their eggs at the base of hair fibers. Hair and body lice are transferred between hosts by personal and clothing contact, whereas crab lice are transmitted by sexual contact.

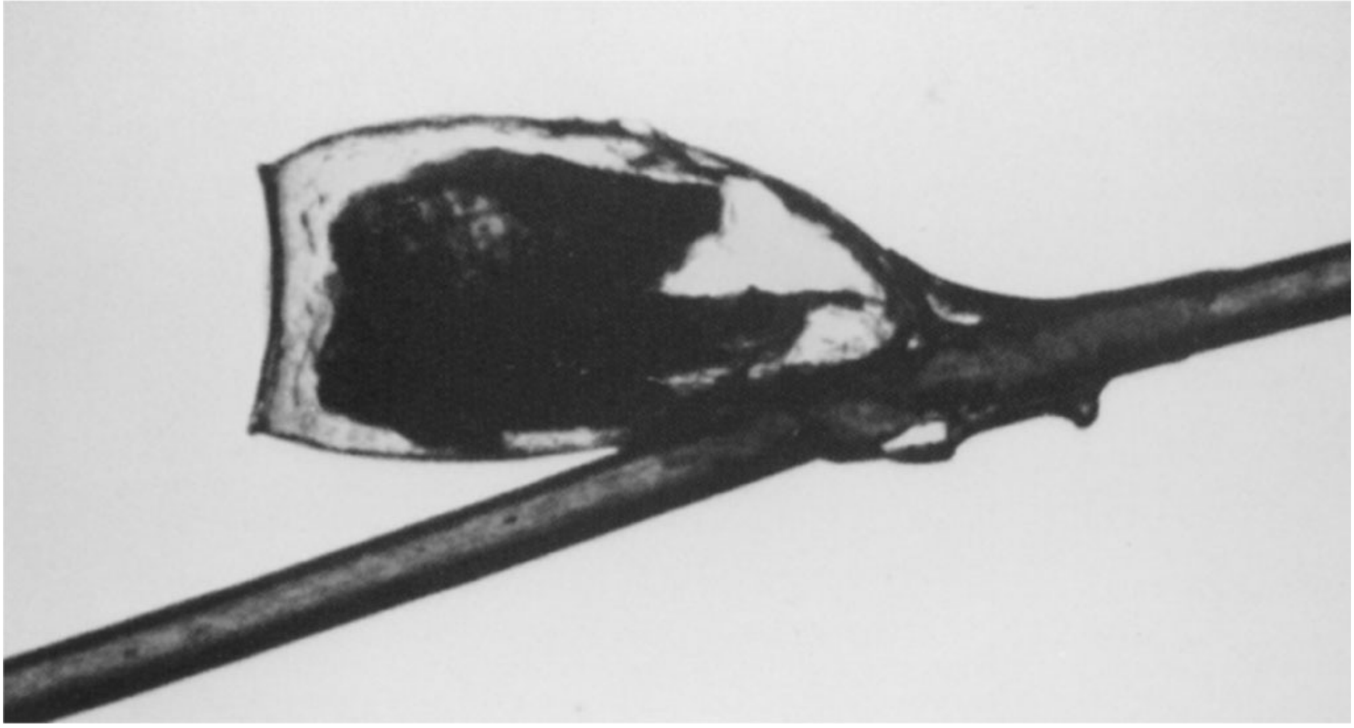

Figure 81-9 Nit or egg of lice on hair shaft.

SIGNS AND SYMPTOMS

CASE 81-11

QUESTION 1: W.L., a 30-year-old homeless man who primarily lives on the streets, presents to a free clinic complaining of intense itching all over his body. Upon examination it is noted that he has a number of pustular lesions all over his body. The skin is particularly thick and discolored around his midsection. The triage nurse says he has "lice all over his body."

Why are the symptoms in W.L. consistent with lice infection?

The most common complaint of patients with head and body lice is pruritus of the scalp, ears, neck, and other body parts. Chronic infestations may result in hyperpigmentation and thickening of the skin. These changes are often seen in the waist, groin, and upper thigh areas ("vagabond's disease"). In severe infestations, intractable itching and scratching can result in folliculitis, hemorrhagic macules or papules, or secondary bacterial infections.[85,91] In contrast, schoolchildren who are exposed frequently to head lice may have only minor pruritus affecting the scalp, ears, and neck.[92]

Treatment

CASE 81-11, QUESTION 2: How should W.L. be treated for lice infection of the head, body, and genital areas?

Concurrent treatment for the pustular bacterial lesions and lice infestation should be initiated in W.L. First-line treatment of head lice in both adults and children is permethrin 1% (Nix) rinse. Alternatives are 0.5% malathion (Ovide) lotion and pyrethrin 0.33% plus 4% piperonyl butoxide (Rid). Recent studies indicate that there may be differences in efficacy among the topical agents. Resistance of head lice to Ovide lotion (0.5% malathion) has been documented in the United Kingdom. The formula used in the United States contains terpineol, dipentene, and pine needle oil, possibly responsible for delaying resistance in the United States.[86,93] Lindane is FDA approved as a second-line therapy because of its neurologic toxicities, and it should be used only when other alternatives have failed (see Table 81-4).[86]

Body lice can be eliminated by bathing and laundering clothing in hot water. Because of W.L.'s severe infestation, he should also apply a topical pediculicide. Products for head lice may be used for body lice with treatment repeated in 7 to 10 days.[85,94] Oral medications such as ivermectin is not FDA approved but has shown to be more effective in some difficult-to-treat cases.[95] First-line treatment of pubic lice is permethrin 1% or pyrethrins plus piperonyl butoxide. Alternative regimes include malathion 0.5% lotion to be rinsed off after 8 to 12 hours or ivermectin 250 mcg/kg to be repeated in 14 days.[96] The pruritus in W.L. can be symptomatically treated with an antihistamine and a low-potency topical steroid.

Several "natural products" such as melaleuca plus lavender oil, coconut oil plus anise oil, tea tree oil, petrolatum shampoo, mayonnaise, and Cetaphil have been used in the management of lice.[97,98] None are FDA approved and have not been proven to be more efficacious. Manual removal of nits by a fine-tooth comb can be a tedious task but necessary because none of the pediculicides are 100% ovicidal. Application of vinegar-based products 3 minutes prior to combing has been reported to make the process of "nit-picking" easier.[86]

Table 81-4

Application of Nonprescription and Prescription Options for Head Lice

Nonprescription products[a,b]	
Product	**Application directions**
Permethrin 1% (Nix)	Apply to damp hair that has been first shampooed with non-conditioning shampoo and towel dried. Leave on for 10 minutes and rinse off Repeat in 7–10 days if live lice are seen (re-treatment at 9 days is optimal) Alternative treatment schedule: 0, 7, and 13–15 days Conditioners and silicon-based products reduce residual effects of permethrin
Pyrethrins plus piperonyl butoxide (Rid) (available as mousse and shampoo)	Apply to dry hair and leave on for 10 minutes prior to rinsing off Retreatment schedules same as permethrin Significant resistance has been developed reducing its effectiveness
Prescription products	
Malathion 0.5% (Ovid) Lotion	Apply to dry hair, let air dry then wash off after 8–12 hours Repeat in 7–9 days if live lice are seen Highly flammable because of alcohol content. Instruct patients to let hair air dry uncovered—do not use hair driers, curling irons, or flat irons while hair is wet Resistance seen in the United Kingdom. Current US formulation differs from European formulation—less resistance seen in the United States
Benzyl Alcohol 5% (Ulesfia)	Apply a sufficient quantity to dry hair to saturate the scalp and the entire length of hair. Leave on for 10 minutes then rinse off Reapplication process is same as for permethrin
Spinosad 0.9% Suspension (Natroba)	Apply to dry hair to saturate the scalp and work out to end of hair (may require the entire contents of bottle). Leave on for 10 minutes and rinse off Retreat in 7 days if live lice are seen
Ivermectin 0.5% Lotion (Sklice)	Apply to dry hair and scalp, leave on for 10 minutes, and rinse off. Only one application is needed

[a] All topical products should be rinsed off over a sink with warm water—not in a shower or bath to limit exposure to the skin.

[b] Nits can be removed from the hair by using a sturdy fine-tooth comb.

There are various treatment options for head lice. Lack of adherence or failure to follow instructions may lead to resistance or failure to eradicate the louse.

Sources: Adapted from: Devore CD, Schutze GE. The Council on school health and committee on infectious diseases. Head lice. Pediatrics. 2015;135(5):e1355–e1365; Centers for Disease Control and Prevention (CDC) Head Lice Treatment. http://www.cdc.gov/parasites/lice/head/treatment.html. Accessed July 31, 2015.

Petrolatum

To remove lice from W.L.'s eyelids or eyelashes, ophthalmic grade petrolatum ointment can be used.[89] Petrolatum is applied to the eyelashes and lid margins with cotton swabs –2 to 4 times daily. This regimen will either suffocate the lice or physically remove them. Use of regular petrolatum may cause irritation to W.L.'s eyes.

Decontamination Measures

Treatment for pediculosis should include thorough decontamination to avoid reinfection. All personal articles of clothing, including bedding, should be washed and dried in temperatures >130°F or 54.4°C.[86] Items that cannot be washed can be dry-cleaned or placed in a plastic bag for 2 weeks. Furniture and carpeting should be vacuumed; pediculicide spray is not recommended. Hairbrushes, combs, and other plastic articles can be decontaminated by soaking in hot water.[99] In institutions and schools where lice infestations are a problem, outer clothing (coats, hats, scarves) of individuals should be isolated in separate plastic bags at the beginning of the day. This measure will reduce reinfection significantly.

SCABIES

Prevalence

Scabies is a contagious skin infestation caused by the female mite, Sarcoptes scabiei var. hominis. Infestations occur throughout the world and across all socioeconomic groups. The mite is transmitted by an infested individual through close skin contact.[96] Crusted scabies (Norwegian scabies), typically seen in immunocompromised individuals, is a more severe form that is highly infectious. Scabies outbreaks are often seen in institutional settings such as nursing homes and prisons.[100] Typical presentation is the presence of a pimple-like rash with intense itching. Those presenting with crusted scabies have thick crusts of skin containing a large number of mites and eggs.

Life Cycle

Adult females deposit eggs and feces (scybala) as they burrow under the skin. Once the eggs hatch, larvae are released which eventually mature to nymphs and adult mites. The female mite can live up to 6 weeks producing 2 to 4 eggs daily. The classic presentation of skin lesions are a result of the burrowing action of the mites and hypersensitivity reactions to their excrement. Most common sites of lesions are in the interdigital finger webs, wrists, elbows, buttock, and genitalia.[101–103]

Treatment

CASE 81-12

QUESTION 1: G.P., a 26-year-old nurse working at a nursing home, presents to her PCP with a pruritic rash with excoriations in the interdigital webs of her hands and wrists. Several patients and nurses in the same nursing home have similar symptoms as well as her 5-year-old son. Burrows were present in her finger webs with a definitive diagnosis made from a skin scraping test. Microscopic examination revealed eggs of S. scabiei and scybala.

How should G.P. and her family be treated? What special instructions and precautions should accompany therapy?

There are several treatment options available for scabies. The treatment of choice in patients 2 months or older is permethrin 5% cream.[102] A thin layer must be applied to the skin from the neck to toes for 8 to 14 hours and then washed off. Although not FDA approved, oral ivermectin 200 mg/kg as a single dose and repeated in 2 weeks is also considered first-line treatment. A repeat dose is needed because of its limited ovicidal activity.[104] Ivermectin is not recommended for children under the age of 5 years of age, <15 kg, pregnant, or lactating women.[102] Lindane should be considered only as a second-line therapy because of reported toxicities.[105] Lindane is useful if first-line therapies are not tolerated or if treatment fails.

Symptoms after exposure to scabies may take several weeks to appear for first-time infections. Sexual partners and any other person who have prolonged contact with an infested individual should be treated.[96] All members of the family should be treated at the same time to avoid reinfestation. Symptoms may persist for up to 2 weeks, if symptoms persist after 2 weeks evaluate for treatment failure.

G.P. must be educated on the non-pharmacologic measures to manage scabies. All bedding and clothing must be washed in hot water (140°F) and hot dried or dry-cleaned. Items that cannot be washed, such as stuffed toys, may be placed in a sealed plastic bag for 48 to 72 hours because mites cannot survive for more than 72 hours away from human skin.[96,106] Fumigation of living areas is not recommended.

ACKNOWLEDGMENT

The authors gratefully acknowledge Lin H. Chen, MD, Division of Infectious Diseases, Mount Auburn Hospital, for her expert review of this chapter.

Tick-Borne Diseases

Caroline S. Zeind, Michelle L. Ceresia, and Lin H. Chen

CORE PRINCIPLES	CHAPTER CASES
LYME DISEASE	
① Lyme disease is a multisystem spirochetal disease caused by the bacterium Borrelia burgdorferi and is transmitted to humans through the bite of infected black-legged ticks. Geography, tick species, and duration of attachment are used to guide clinical decision-making.	**Case 82-1 (Question 1)**
② Although clinical features of Lyme disease are diverse and vary with the stage and duration of infection, the presence of an erythema migrans (EM) skin rash is universally the most common feature.	**Case 82-2 (Questions 1, 2)**
③ Most cases of localized (early) Lyme disease can be treated effectively with a few weeks of antibiotics (range of 10–21 days); however, if left untreated, infection can spread to the joints, the heart, and the nervous system.	**Case 82-2 (Question 3, 4),** **Case 82-3 (Question 1),** **Case 82-4 (Question 1)**
RELAPSING FEVER	
① Relapsing fever is a bacterial infection caused by certain species of Borrelia spirochetes. Of the two types of relapsing fever, tick-borne relapsing fever (TBRF) occurs in the western US and louse-borne relapsing fever (LBRF) is generally restricted to refugee settings in developing parts of the world.	**Case 82-6 (Question 1)**
BORRELIA MIYAMOTOI	
① Borrelia miyamotoi is a recently identified tick-borne organism transmitted by Ixodes ticks and is endemic in the same areas as Lyme disease, anaplasmosis, and babesiosis.	**Case 82-6 (Question 2)**
SOUTHERN TICK-ASSOCIATED RASH ILLNESS	
① Southern tick-associated rash illness (STARI) is a tick-borne disease transmitted by the lone star tick and whose etiology is unknown. Patients bitten may occasionally develop a rash similar to the rash of Lyme disease.	**Case 82-7 (Question 1)**
ANAPLASMOSIS	
	Case 82-8 (Question 1)

1	Anaplasmosis, a tick-borne disease caused by the bacterium, Anaplasma phagocytophilum, was first recognized as a disease of humans in the United States in the mid-1990s. If not treated appropriately, illness can be severe and potentially fatal.	

BABESIOSIS

1	Babesiosis is an illness caused by parasites that infect red blood cells and are spread by certain ticks, with symptoms ranging from asymptomatic disease to potential fatality, especially in immunocompromised patients.	**Case 82-9 (Questions 1, 2)**

COLORADO TICK FEVER, TICK-BORNE ENCEPHALITIS, AND OTHER VIRALLY MEDIATED TICK-BORNE DISEASES

1	Colorado tick fever (CTF) is a virally mediated tick-borne disease that can be more severe in children than in adults. Other virally medicated tick-borne diseases include those caused by Powassan, Bourbon, and Heartland viruses.	**Case 82-10 (Question 1)**

TICK PARALYSIS

1	Tick paralysis occurs worldwide, affecting humans and livestock. It can be reversed by tick removal.	**Case 82-11 (Question 1)**

PREVENTION OF TICK-BORNE ILLNESSES

1	Prevention of tick-borne diseases is always preferable to acquisition. Personal protective measures and other methodologies aid in prevention.	**Case 82-5 (Question 1)**

OVERVIEW

Currently, the majority of emerging infectious diseases are arthropod-borne and are caused by ticks and mosquitoes.[1] Unfortunately, with few exceptions, these emerging diseases cannot be prevented by vaccinations. Ticks belong to the class Arachnida, which includes scorpions, spiders, and mites.[2] Tick-borne diseases are a growing problem worldwide, transmitting pathogens that cause diseases in humans and animals.[3] As a vector of human illness worldwide, disease can be spread by ticks, either by transmission of microorganisms or by injection of tick toxin into a host. Bacterial, rickettsial, protozoal, and viral disease pathogens can be transmitted from ticks to humans (Table 82-1).[4,5]

Table 82-1

Tick-Borne Diseases

Disease	Causative Agent	Tick Vector	Host	Endemic Areas	Comments
Bacterial					
Anaplasmosis (Human granulocytic anaplasmosis (HGA))	Anaplasma phagocytophilum	Ixodes scapularis, Ixodes pacificus	Deer, elk, wild rodents	North America (upper Midwest and northeastern US)	Previously was known as human granulocytic ehrlichiosis (HGE) Reported in areas that correspond to the known geographic distribution of Lyme disease treatment: same as ehrlichiosis and RMSF
Ehrlichiosis	Ehrlichia chaffeensis, Ehrlichia ewingii, Ehrlichia muris-like (EML)	Amblyomma americanum	Deer, dogs	North America (southeastern and south-central US, from the eastern seaboard extending westward to Texas)	Similar clinical presentation as anaplasmosis but transmission by two different species of ticks and typically occur in different US regions New species EML was identified in 2009 in patients in the upper Midwest Treatment: same as anaplasmosis and RSMF
Lyme Disease	Borrelia burgdorferi Borrelia mayonii	Ixodes scapularis, Ixodes pacificus	Wild Rodents	North America: Borrelia burgdorferi; Borrelia mayonii (new species identified in Midwestern US; genetically distinct from Borrelia	Worldwide caused by three main species of bacteria: Borrelia burgdorferi (North America), and in Europe and Asia: B. afzelii,

				burgdorferi, B. afzelii, and B. garinii) Europe: more common in eastern and central Europe Asia: northern Asia B. afzelii, and B. garinii	and B. garinii
Borrelia Miyamotoi Disease (BMD)	Borrelia miyamotoi	Ixodes scapularis; Ixodes pacificus			First BMD cases identified in North America in 2013
Tick-borne Relapsing Fever (TBRF)	Borrelia species Borrelia hermsii, B. parkerii, or B. Turicatae	O. hermsii ticks; O. parkerii, and O. turicata	Rodents	North America (western states in the United States); Central America, South America, the Mediterranean, Central Asia, and much of Africa	Most cases occur in summer months in rodent-infested cabins but can occur in winter months when fires warming a cabin activate ticks resting in the walls/woodwork
Tick-borne Spotted Fever Rickettsial Infections, broadly grouped as "Spotted Fever group Rickettsia" (SFGR)[a]	Rickettsia species Rickettsia parkeri Worldwide: Rickettsia species including R. conorii and R. africae	various ticks depending on Rickettesia species		North America: United States: R. parkeri (Eastern and southern US); and Rickettsia species 364D (Northern California, Pacific coast) Worldwide: all continents except Antarctica; numerous Rickettsia species including R. conorii and R. africae	
Rocky Mountain Spotted Fever (RMSF)	Rickettsia rickettsia	Dermacentor variabilis, Dermacentor andersoni, Rhipicephalus sanguineus	Wild rodents, ticks	North America: United States >60% of cases occur in North Carolina, Oklahoma,	United States: Reported throughout most of the contiguous states

				Arkansas, Tennessee, and Missouri; reports increasing in certain parts of Arizona	Treatment: same as anaplasmosis and ehrlichiosis.
Tularemia	Francisella tularensis	Dermacentor variabilis, Dermacentor andersoni, Amblyomma americanum	Rabbits, hares, and rodents; domestic cats	Most common in the south-central US, the Pacific Northwest, and parts of Massachusetts	United States: reported from all states except Hawaii Other transmission routes: inhalation and direct inoculation
Parasitic					
Babesiosis	Babesia species (most cases Babesia microti)	Ixodes scapularis	Mice, voles	North America (northeastern and upper Midwestern US where Babesia microti is endemic); also sporadic cases on West Coast	Transmission of Babesia parasites can occur by transfusion
Viral					
Colorado tick fever	Coltivirus species	Dermacentor andersoni	Wild rodents, mammals	North America: western US and southwestern Canada (at elevations of 4,000 to 10,000 feet)	Transmission can occur from person to person (rare)
Heartland virus	Phleboviruses	Amblyomma americanum		United States: Missouri and Tennessee	Worldwide

Tick-borne Encephalitis	Member of virus family Flaviviridae	Ixodes ricinus, Ixodes persulcatus	Rodents	Europe: temperate regions, forested areas Asia: northern Asia (temperate regions, forested areas)	May also be acquired by ingestion of unpasteurized dairy products from infected cows, goats, and sheep
Powassan virus	Member of virus	Ixodes scapularis,		North America:	

	family Flaviviridae	Ixodes cookei		United States (northeastern states and Great Lakes region), Canada Europe: Russia	
Crimean–Congo Hemorrhagic Fever (CCHF) Virus	Nairo virus. Family Bunyaviridae	Ixodid ticks		Asia, Africa, and Europe	May also be inquired by contact with infected blood, saliva, or inhalation
Omsk Hemorrhagic Fever Virus (OHFV)	Member of virus family Flaviviridae	Dermacentor reticulatus, Dermacentor marginatus, Ixodes persulcatus		Europe: southwestern Russia	
Kyasanur Forest Disease Virus (KFDV)	Member of virus family Flaviviridae	Hemaphysalis spinigera (hard ticks)		Asia: southern India, Saudi Arabia (aka Alkhurma disease in Saudi Arabia)	Associated with exposure while harvesting agents
Other					
Southern Tick-Associated Rash Illness (STARI)		Amblyomma americanum		Eastern, southeastern, and south-central US

Tick Genus

Only two of the three families of ticks are of medical significance to humans: the soft-bodied ticks, Argasidae, and the hard-bodied ticks, Ixodidae.[2] Four of the 13 genera of Ixodidae transmit disease in the United States: Dermacentor, Ixodes, Amblyomma, and Rhipicephalus. Among the five genera of Argasidae, only Ornithodoros are known to transmit pathogens to humans in the United States. Most hard ticks have a 2- to 3-year life cycle, comprising the larval, nymphal, and adult stages.[2] They require one blood meal during each stage before they can mature into the next stage, and they usually remain attached to a host for hours or days. In contrast, soft ticks may have multiple nymphal stages, and both nymphal and adult forms can feast on blood multiple times, usually for only 30 minutes. However, Argasidae can survive many years without blood sustenance and are long-lived.[2]

Humans are the inadvertent hosts for the life cycle of almost all ticks and tick-borne diseases.

LYME DISEASE

Lyme disease, or more accurately Lyme borreliosis, is a multisystem spirochetal disease caused by several genospecies of the spirochete Borrelia burgdorferi sensu lato.[5,6] Lyme disease, which is transmitted by a tick bite, was first recognized in the United States in the mid-1970s, after a mysterious outbreak of arthritis near Lyme, Connecticut.[6] However, illness consistent with late manifestations of Lyme disease was described in Europe more than a century ago. In Europe and North America, Lyme disease is now recognized as the most commonly reported vector-borne disease.[6]

Etiologic Agent

Three genomic subgroups of B. burgdorferi worldwide account for most human infections: B afzelii, B garinii, and B burgdorferi sensu stricto (hereafter referred to as B burgdorferi).[6,7] Although all three groups have been found in Europe, most isolates are Borrelia garinii or Borrelia afzelii, the North American strains identified to date belong to the B. burgdorferi as the cause of Lyme disease.

Tick Vectors

There are four species of Ixodes ticks that commonly bite humans. In Europe and Asia, I ricinus and I persulcatus are principal vectors, respectively. In the United States, the black-legged or deer tick, I scapularis, is the principal vector in areas of the Northeastern, Mid-Atlantic, and North Central states, whereas I. pacificus, the western black-legged tick, is the principal human-biting vector in the western US.[6,7]

The tick acquires the B. burgdorferi spirochete from feeding on an infected reservoir host, such as mice, shrews, and other small mammals and various species of birds. The spirochete remains dormant in the tick's midgut until the tick feeds again. The spirochete then passes through the salivary ducts of the tick and is injected through the skin of the new host with the tick bite.[6,8,9]

Few spirochetes are transmitted from the tick to its host during the first 24 to 36 hours of attachment. An infected nymphal tick, however, invariably transfers spirochetes when attached to its host for more than 72 hours.

Most humans are infected through the bites of nymph ticks, which feed during the spring and summer months. Larval and nymph ticks are small, less than 3 mm, size of a freckle or poppy seed. Therefore, the tick often goes unnoticed, and fewer than half of patients with Lyme disease recall having been bitten by a tick. The tick feeds on small, medium, or large mammals, lizards, or birds during its larval and nymphal (immature) stages.[2] Larval ticks are not relevant vectors for Lyme disease, however, because they are rarely infected and become so only after feeding on an infected host.[3] Adult ticks parasitize only medium or large mammals.[2] Although adult ticks can also transmit Lyme disease bacteria, because they are much larger, individuals are more likely to discover and remove them prior to transmission of bacteria.

Humans are inadvertent hosts of any stage of the tick. Although the tick can feed on many different animals, each tick species has preferred hosts. The complex interplay of spirochete, host, and vector in a particular area influences the risk of Lyme disease after a tick bite. Lyme disease is not transmitted directly between people, and there has not been substantive evidence of human transmission through sexual contact, semen, urine, or breast milk.[6]

Clinical Features and Diagnosis

LOCALIZED (EARLY) STAGE

Although clinical features of Lyme disease are diverse and vary with the stage and duration of infection, the presence of an EM skin rash is universally the most common feature, occurring in 60% to 90% of cases in North America.[6] The development of an EM rash at the site of the tick bite is typically the first indication of transmission and early infection in most North American patients.[8] The EM rash, which reflects the innate immune response, occurs between 3 and 30 days (an average of 7 days). Fever, headache, fatigue, muscle and joint aches, and swollen lymph nodes, and the characteristic EM skin rash are the typical early signs and symptoms (3 to 30 days after the tick bite).[4]

Lyme disease is diagnosed based on patient symptoms, physical findings (e.g., EM rash), and the possibility of tick exposure.[4,8–10] Because it is a multisystem condition, if left untreated, infection can spread to the joints, the heart, and the nervous system. Although laboratory methods can be helpful if used correctly, serologic tests are insensitive during the first few weeks of infection. Though not necessary, in some cases, acute and convalescent titers may be helpful in some cases. During this stage, patient with an EM rash, systemic symptoms, and the possibility of tick exposure may be diagnosed clinically. Appropriate antibiotics should be initiated in early stages of Lyme disease.

DISSEMINATED STAGE

During the disseminated stage, serologic tests are usually positive and a standardized two-tier testing protocol is recommended.[4,8,11] The Lyme disease presentation and testing can be complex, and the reader is referred to the Centers for Disease Control and Prevention (CDC) and other resources for further information.[4] During this stage, a variety of manifestations may occur (Table 82-2).

Treatment

The clinical manifestations of Lyme disease should govern the treatment strategy.[4,11] Patients who receive appropriate treatment in the early stages of Lyme disease usually recover rapidly and completely. Oral treatment regimens commonly used in early-stage disease include doxycycline, amoxicillin, or cefuroxime axetil (Table 82-3).[5] Patients with disseminated (late) Lyme disease should be evaluated for severity and may require intravenous treatment.[4,11]

CASE 82-1

QUESTION 1: C.J., a 32-year-old male, visits his primary care physician (PCP) with symptoms of low-grade fever and muscle aches 2 days after camping in the western part of Massachusetts during the month of August. He explained that he was canoeing and hiking with his family in the woods, and on the last day of their trip, he noticed a small tick on his thigh and immediately destroyed it. A small, itchy spot that he felt at the site of the tick bite is no longer symptomatic. C.J. asks his PCP whether he needs any laboratory tests and/or preventive treatment. Given his presentation and tick bite history, what would be appropriate steps to management?

Table 82-2

Lyme Disease Clinical Manifestations

Early Localized Stage

- Erythema migrans (EM) skin rash: red ring-like or homogenous expanding rash
- Flu-like symptoms—malaise, headache, fever, myalgia, arthralgia
- Lymphadenopathy

Disseminated Stage

- Flu-like symptoms
- Lymphadenopathy
- Multiple secondary annular rashes

Cardiac Manifestations

- Myocarditis or pericarditis
- Conduction defects, varying degrees of atrioventricular or bundle-branch block, but permanent pacing not indicated

Neurologic Manifestations

- Bell’s palsy or other cranial neuropathy
- Meningitis
- Radiculoneuritis, myelitis

- Sensory or motor peripheral neuropathy

Rheumatologic Manifestations

- Transient, migratory arthritis and effusion in one or multiple joints
- Migratory pain in tendons, bursae, muscle, and bones
- Baker cyst
- Arthritis may recur in same or different joints (if untreated)

Additional Manifestations

- Conjunctivitis, keratitis, uveitis
- Mild hepatitis
- Splenomegaly

Source: Centers for Disease Control and Prevention. Tickborne Diseases of the United States. A Reference Manual for Health Care Providers. 3rd ed. 2015.

The routine use of antibiotic prophylaxis or serologic testing is not recommended for Lyme disease prevention following a recognized tick bite.[4,11] With regard to C.J.'s situation, the use of serologic testing is not recommended because the antibody response to B. burgdorferi is not detectable for the first few weeks after a tick bite. Therefore, the blood tests for antibodies to B. burgdorferi are unlikely to be positive, because C.J.'s tick bite occurred only 2 days ago.[8,10,11]

Table 82-3

Treatment Recommendations for Localized (Early) Lyme Disease

Adults: doxycycline 100 mg, 2 times/day orally × 14 days (14–21 days)
Or
Amoxicillin 500 mg, 3 times/day orally × 14 (14–21 days)
Or
Cefuroxime axetil 500 mg, 2 times/day orally × 14 (14–21 days)
Children: amoxicillin 50 mg/kg/day orally, divided into three doses (maximum, 500 mg/dose) × 14 days (14–21 days)
Children: cefuroxime 30 mg/kg/day, orally, divided into two doses (maximum, 500 mg/dose) × 14 days (14–21 days)
Children (>8 years): may use doxycycline 4 mg/kg/day orally, divided into two doses (maximum, 100 mg/dose) × 14 days (14–21 days)

Sources: Centers for Disease Control and Prevention. Tickborne Diseases of the United States. A Reference Manual for Health Care Providers. 3rd ed. 2015; Wormser GP et al. The clinical assessment, treatment, and prevention of Lyme Disease, Human Granulocytic Anaplasmosis, and Babesiosis: clinical practice guidelines by the Infectious Diseases Society of America. [published correction appears in Clin Infect Dis. 2007;45(7):941]. Clin Infect Dis. 2006;43:1089–1134.

The risk of developing Lyme disease can be affected by the rate of transmission of the spirochete from infected ticks to humans, the length of time before the tick is removed during its bite, the degree of blood engorgement of the tick (scutal index), the prevalence of spirochete infestation of ticks in an area (which varies with the tick species), and the reservoir competency of host animals in the region.[3]

Although transmission rates of Lyme disease from an infected tick bite are estimated at approximately 10%, the risk is reduced dramatically if the tick is removed within 24 hours of attachment. The small, itchy spot experienced by C.J. may represent a hypersensitivity reaction to the bite. These erythematous, noninfectious skin lesions develop within 48 hours of tick detachment or may occur while the tick is still attached. They are usually less than 5 cm in diameter; they may have an urticarial appearance and usually disappear in 1 or 2 days.[4,6]

Prophylactic antibiotic preventive therapy with a single dose of 200 mg of oral doxycycline (children 8 years or older at 4 mg/kg to a maximum 200-mg dose) can be offered if all of the following criteria are met: (a) There are no contraindications to doxycycline use; (b) administration can start within 72 hours of tick removal; (c) the tick can be reliably identified as a nymphal or adult I. scapularis tick with certainty of the duration of attachment of 36 hours or more based on the degree of engorgement or time of exposure; and (d) the local rate of infection of ticks by B. burgdorferi in the area of exposure is 20% or greater based on current ecologic evidence.[3] Routine testing of ticks themselves for tick-borne infections is not recommended.[11]

Antibiotic prophylaxis after I. pacificus tick bites is generally not necessary because of relatively low prevalence of B. burgdorferi infestation of I. pacificus ticks.[11] However, C.J. had exposure in a region where B. burgdorferi is highly prevalent among I. scapularis ticks. If there is uncertainty regarding the duration of tick attachment, he may be offered a dose of doxycycline prophylaxis.

ERYTHEMA MIGRANS

Signs, Symptoms, and Disease Course

CASE 82-2

QUESTION 1: M.K., a 37-year-old woman, presents with right knee pain and multiple, large, discrete skin rashes that she has had for the past 10 days. Three months ago, in July, she visited friends in Maine and spent much of her time engaged in outdoor activities. Two months ago, her husband noticed a circular area of intense redness, approximately 9 cm wide, in her left armpit. The rash grew considerably larger during the next 2 weeks and had a red outer border. M.K. attributed the expansion of the rash to having scratched the mildly itchy area. The rash gradually disappeared. In late August, M.K. experienced fatigue, nausea, and headache for a week and thought it was “summer flu.” In early September, she experienced right knee pain; ibuprofen produced some relief.

On examination, she was afebrile and had mild soft tissue swelling of the right knee. Her white blood cell (WBC) count was normal. Serum samples contained antibody titers to B. burgdorferi demonstrated by a sensitive ELISA (enzyme immunoassay) followed by a Western blot for immunoglobulin M (IgM) and IgG. A Venereal Disease Research Laboratory (VDRL) test for syphilis and a pregnancy test were negative.

M.K. is started on a 4-week course of oral doxycycline 100 mg twice daily. What characteristics of M.K.’s skin rash are consistent with the EM of Lyme disease?

The EM of Lyme disease usually develops within 3 to 30 days (average 7 days) of a usually asymptomatic tick bite at the site of inoculation of the spirochete. The rash begins as an erythematous (red) macule or papule typically on the thigh, back, shoulder, calf, groin, popliteal fossa, flank, axilla, buttock, or upper arm.[4,6,11] In children, EM is often found on the head at the hairline, neck, arms, or legs. It expands outwardly at 2 to 3 cm/day to a diameter of 5 to 70 cm (mean, 16 cm), occasionally with some central clearing. Some cases of EM in the United States lack central clearing. The rash may be warm to the touch and is usually painless, but some patients have mild burning or itching. Up to 50% of patients with EM have multiple secondary lesions that most likely represent blood-borne spread of the spirochete to other skin sites rather than multiple tick bites.[5] If untreated, EM generally fades within several weeks; if treated, it usually resolves in several days.[4,6,11]

Low-grade fever and other nonspecific symptoms, such as malaise, headache, myalgias, or arthralgias, may accompany EM.[4,6,11] Some individuals may have no symptoms. Cough, rhinitis, sinusitis, and other respiratory symptoms do not usually occur in Lyme disease.[4] Pitfalls in the diagnosis of EM exist. Lesions are sometimes misdiagnosed. M.K.'s skin rash was large (>9 cm), red, and had a red outer border. It gradually faded over the course of a few weeks. These characteristics are consistent with a diagnosis of EM.

Serologic Testing

CASE 82-2, QUESTION 2: What might have been the rationale for the laboratory tests that were undertaken in M.K.?

Guidelines currently recommend a two-tier approach of ELISA and confirmatory Western blotting.[8,10,11] The sensitivity of such testing in Lyme arthritis cases is 97% to 100%.[9,11] However, routine use of serology testing for patients with early EM cannot be recommended presently. Syphilis and other known biologic causes (periodontal spirochetes) of false-positive serologic testing should

---

be excluded. Rheumatoid factor or antinuclear antibody tests usually are negative in Lyme disease. These tests help differentiate rheumatoid arthritis or systemic lupus erythematosus from Lyme disease. The WBC count is normal or mildly elevated in Lyme disease. M.K. had a normal WBC. Pregnancy was ruled out before initiating a tetracycline. Most interesting in M.K. is the presence of secondary EM lesions representing disseminated infection.

The presence of EM as an early indicator of Lyme disease gives clinicians the best opportunity for early diagnosis and treatment.[4,11] In the United States, the expression of EM is the only manifestation of Lyme disease that is sufficiently distinctive to allow clinical diagnosis in the absence of confirmatory laboratory information.[4,11] Early treatment can prevent sequelae of disseminated disease.

LYME DISEASE TREATMENT

Antibiotics

CASE 82-2, QUESTION 3: Why was doxycycline selected to treat M.K.?

Borrelia burgdorferi is susceptible to amoxicillin, tetracyclines, and some second- and third-generation cephalosporins. It is only moderately sensitive to penicillin G and is resistant to first-generation cephalosporins, rifampin, cotrimoxazole, aminoglycosides, chloramphenicol, and the fluoroquinolones.[4,11]

Penicillin, tetracycline, and erythromycin historically were the drugs of choice for the treatment of Lyme disease because they can be administered orally; they are relatively inexpensive and appear to have good in vitro activity. However, this in vitro activity does not translate to in vivo efficacy. Doxycycline is an agent of choice for treatment of Lyme disease. Amoxicillin and cefuroxime axetil are also first-line options. In Europe, in contrast, penicillin still is used with continued success. A nondoxycycline regimen is preferred in pregnant or breast-feeding women and in children younger than 8 years of age.[4,11]

Compared with the third-generation cephalosporins, the oral second-generation drug cefuroxime axetil has good in vitro activity and efficacy. But it is more expensive than oral amoxicillin or doxycycline. Of the third-generation cephalosporins, ceftriaxone has the most potent in vitro activity and a long half-life for once-daily dosing in an outpatient program. Ceftriaxone is expensive, however, and has a higher incidence of diarrhea than other β-lactams, probably owing to extensive biliary excretion.

The macrolides clarithromycin and azithromycin are unpredictable in their in vitro activity.[4,11] Similar to erythromycin, they are less effective in the treatment of Lyme disease. The combination of a macrolide with lysosomotropic agents, especially hydroxychloroquine, anecdotally has been suggested to be associated with increased symptom relief probably related to combined anti-inflammatory activity rather than direct antimicrobial activity.[3] Doxycycline is well absorbed orally and is less expensive than parenteral ceftriaxone or cefotaxime. Doxycycline has a long serum half-life of 18 to 22 hours. In addition, doxycycline penetrates into the cerebrospinal fluid (CSF) at concentrations of at least 10% of serum levels, even in the absence of meningeal inflammation. Although not as significant as with tetracycline, doxycycline can complex with divalent or trivalent cations in the gut, with an associated decrease in oral absorption. On the other hand, administering doxycycline with food, to minimize nausea, is recommended.[3] Compared with other tetracyclines, doxycycline has the least affinity for divalent calcium cations, and oral absorption is reduced by only 20% if given with milk. The major side effect of doxycycline is phototoxicity, which is of concern because Lyme disease usually occurs during sunny times of the year. A less recognized side effect is the risk of doxycycline-induced esophageal ulceration. Patients should be instructed to never take doxycycline or other tetracyclines near bedtime and to take the medication while standing up with at least 240 mL of clear fluid, especially with the capsule formulation. Despite less in vitro activity compared with some β-lactam antibiotics, B. burgdorferi is sufficiently susceptible to doxycycline, and clinical experience with doxycycline has been very favorable. In conclusion, doxycycline was a suitable choice for M.K.

Chronic Lyme Arthritis

CASE 82-2, QUESTION 4: M.K. continues to have knee inflammation for 3 months after receiving a second course of antibiotic treatment and is now considered to have Lyme arthritis. Should antibiotic therapy be repeated for M.K.'s arthritis?

Acute Lyme arthritis occurs from the accumulation of neutrophils, cytokines, immune complexes, complement, and mononuclear cells induced by the spirochete.[12] Appropriate antimicrobial treatment of acute Lyme arthritis is usually successful, and doxycycline, amoxicillin, or cefuroxime axetil is recommended for adult patients, such as M.K., if there is no clinical evidence of neurologic disease.[11] Treatment for Lyme arthritis typically requires 28 days of therapy.[11] A minority subset of patients may have persistent Lyme arthritis.[12] It is very unlikely that this is attributable to the continued presence of B. burgdorferi in the joint, but rather to the patient's continued inflammatory response or autoimmunity.[12] Polymerase chain reaction (PCR) testing of synovial fluid can be considered, and if negative, symptomatic therapies may be offered rather than repeated antibiotic courses. Such patients often respond well to synovectomy, suggesting that the presence of synovitis may not be the result of persistence of the infection. Nonsteroidal anti-inflammatory agents, disease-modifying antirheumatic agents, intra-articular corticosteroid injections, or synovectomy may be offered.[3,11] However, it should be noted that before the antibiotic treatment era for Lyme disease, even the most prolonged cases of persistent Lyme arthritis eventually improved without treatment, although sometimes lasting for months to years.[12]

Neurologic Lyme Disease

CASE 82-3

QUESTION 1: E.T., a 57-year-old female, presents to her PCP with symptoms of early neurologic Lyme disease, including mild memory and cognitive deficits. Serum two-tier IgG seropositivity was confirmed. Should E.T. be treated with antibiotics? If so, how long should she be treated?

Although rare, late neurologic complications of Lyme disease may present as encephalopathy, peripheral neuropathy, or encephalomyelitis.[4,11] Although the Lyme Borrelia species found in Europe do not strictly overlap with those species found in the United States, there are no data to support a differential response to antibiotic.[10] Based on these studies, oral doxycycline can be considered as first-line therapy for neurologic Lyme disease in Europe and for ambulatory patients with early neurologic Lyme disease in the United States. An oral antibiotic treatment regimen may suffice in cases of early neurologic disease, but parenteral regimens are appropriate for severe cases.[13] In conclusion, E.T. can be treated with doxycycline administered orally and should be reassessed following treatment.

Post-Lyme Disease Syndromes

CASE 82-4

QUESTION 1: A friend who has been treated with a 4-week course of antibiotics for Lyme disease calls you to say that she has lingering symptoms and she thinks it's "chronic Lyme disease." She'd like more information about it. How should you respond?

Chronic Lyme disease is a confusing term, and most authorities agree that there may be "Post-Treatment Lyme Disease Syndrome," (PTLDS).[4] Although the exact cause is unknown, most medical experts believe that the lingering symptoms that can occur are the result of residual damage to tissues and the immune system. Clinical findings in patients may include fatigue, widespread musculoskeletal pain, cognitive difficulties, or subjective symptoms of such severity that a substantial reduction in quality of life has occurred. The subjective symptoms must include an onset within 6 months of the initial Lyme disease diagnosis and persistence for at least 6 months after completion of antimicrobial therapy. If adherence to a recommended Lyme treatment regimen is confirmed, the existence of symptomatic, chronic infection by B. burgdorferi is difficult to confirm. After appropriately targeted antibiotic therapy for early Lyme disease, treatment failure is exceedingly rare. The organism has not been shown to develop antibiotic resistance.[3] For these patients with chronic subjective symptoms for more than 6 months, repeated or prolonged antibiotic therapy is not useful or recommended.[4,11]

The friend should be encouraged to seek additional diagnostic workup for other diseases. Even in patients who have had verified Lyme disease, the aches and pains of daily living they experience appear to be more related to their post-treatment symptoms than to Lyme disease itself.[4]

Lyme Disease Prevention

CASE 82-5

QUESTION 1: A family living in a Lyme disease endemic area is concerned regarding their risk for contracting the disease. How would you advise them on Lyme disease prevention and overall protection from tick-borne disease?

Although some vector-borne diseases are prevented through vector control, this has proven difficult for tick-borne diseases because of a lack of efficacy or environmental concerns with the use of pesticides. Evaluated methods include habitat destruction by fire, chemical spraying agents such as acaricides to achieve tick eradication, culling or removal of host deer, or protection of mice from tick infestation.[13]

Currently, there are limited vaccines available for tick-borne and mosquito-borne illnesses.[14] A Lyme disease vaccine for humans is no longer available in the United States. Citing low demand, the U.S. manufacturer discontinued production in 2002. Clinical trials are currently underway for candidate Lyme borreliosis vaccines.[15]

The first step in prevention of Lyme disease is personal protection and tick avoidance.[16,17] Tick repellents may be applied to the skin or clothing. One basic chemical category of insect repellant is the synthetic agents, such as N,N-diethyl-μ-toluamide (DEET), picaridin (also known as icaridin in Europe), and insect repellent (IR) 3535 (ethyl butylacetylaminopropionate). The second chemical category of repellant is the plant-derived oils and synthetics, such as oil of lemon eucalyptus or PMD (para-menthane-3,8-diol), which is an extract of the leaves of lemon eucalyptus, Corymbia citriodora, a synthesized version of oil of lemon eucalyptus.

The use of DEET skin repellent has evolved as the standard repellant for mosquito and tick-borne diseases. In combination with a permethrin clothing, DEET appears to offer adequate protection. DEET has been tested against Ixodid ticks for repellence and is more effective than dibutyl phthalate, dimethyl phthalate, pyrethrum, and two combination products.[16,17] DEET is generally safe; however, excessive DEET application has been associated with seizures in children.[17,18] These are rare events, however, and if the products are used according to their labeling, the adverse reaction risk is low, even for children older than 2 months of age.[3] Prolonged or excessive application is not recommended. It may be prudent to use the lowest effective concentration of DEET-containing repellents, such as those containing 20% to 30%. To minimize DEET toxicity, the product should be applied sparingly, inhalation or introduction into the eyes should be avoided, repellent-treated skin should be washed when coming inside, use on children's hands (that are likely to have contact with the eyes or mouth) should be avoided, and it should be applied only to intact skin or clothing.

Picaridin was developed in Europe in the 1990s and released in the United States about 10 years ago. A couple of advantages over DEET include the lack of a chemical odor and its nonsticky or greasy feel. It is also safe to use on plastics, whereas DEET may damage certain synthetics including eyeglass frames. IR3535, originally marketed in the United States as a skin emollient and moisturizer, was then adopted for use as an insect repellant. Plant-derived IRs, such as oil of lemon eucalyptus or PMD, have demonstrated efficacy against the tick vectors of Lyme disease (Ixodes scapularis, Ixodes pacificus) and Rocky Mountain spotted fever (Dermacentor andersoni).[1]

A literature review between 2000 and 2012 on the efficacy of repellants against various mosquito and tick species noted that there are only limited studies conducted on tick behavior and repellant efficacy against the tick species Ixodes.[18,19] The use of picaridin, IR 3535, and PMD were also reviewed as part of this study. Results of this study found that the use of IR 3535 provided the longest protection against Ixodes scapularis, whereas DEET and commercial products containing picaridin or PMD demonstrated a better response than IR 3535 against Ixodes ricinus.[18] In situations in which environmental exposure to disease-transmitting ticks, biting midges, sandflies, or blackflies is anticipated, topical repellants containing IR 3535, picaridin, or oil of eucalyptus (or PMD) would offer better protection than topical DEET alone.[1] (Refer to Chapter 81, Parasitic Infections, Table 81-2, Mosquito Protection Measures for additional information on insect repellants).

Physical barriers to ticks, such as wearing protective garments—long pants, and long-sleeved shirts—tucking shirts into pants and pants into boots, and wearing closed-toed shoes, prevent infection.[1] Ticks are easier to spot on light-colored clothing. Checking the body for ticks regularly is recommended; any that are found should be promptly removed. Avoiding tick habitats is the best protection against tick-borne diseases. Effective postexposure antibiotic prophylaxis can be administered in Lyme disease endemic areas after a tick bite.

RELAPSING FEVER

Relapsing fever, a bacterial infection caused by a variety of Borrelia species, causes episodes of fever, nausea, headache, and muscle and joint aches. Of the two types of relapsing fever, tick-borne relapsing fever (TBRF) occurs in the western US and louse-borne relapsing fever (LBRF) is generally restricted to refugee settings in developing parts of the world.[5]

Tick Vector

The predominant tick vector for relapsing fever is of the genus Ornithodoros, a soft-bodied tick. These ticks feed on wild rodents or domestic animals and, incidentally, on humans. In North America, three tick species carry the agents of endemic relapsing fever with apparent strict specificity. In fact, the names of the responsible Borrelia species have been adopted from the three tick species that transmit them: Ornithodoros hermsii, Ornithodoros parkeri, and Ornithodoros turicata.[20] Although the ticks themselves may serve as reservoir hosts, the Borrelia usually circulate among wild rodents, ticks, and possibly birds.[5] Similar to Lyme disease, greater worldwide variations of endemic cycles and vectors for TBRF may exist than in North America.

TICK GEOGRAPHY

In North America, relapsing fever is an uncommon disease largely confined to the geographic distribution of the tick species that harbor the Borrelia. In the United States, most cases of TBRF have occurred in 14 western states and are caused by B. hermsii.[5] These ticks are usually found in the remote natural settings of the mountains and semiarid plains of the far west and Mexico. TBRF can develop when people visit tick- or rodent-infested cabins or summer homes. While TBRF is spread by multiple tick species, Ornithodoros hermsii is the tick responsible for most cases in the United States usually at altitudes of 1,500 to 8,000 feet. The health significance of O. parkeri and O. turicata transmits its Borrelia at lower altitudes in the Southwest, where they inhabit caves and the borrows of ground squirrels, prairie dogs, and burrowing owls.

SPIROCHETAL BEHAVIOR

Ticks acquire spirochetes from blood feeding on small wild rodents. If high levels of Borrelia are present in the animal's blood, large numbers of spirochetes will be ingested by the tick and reside in the tick's midgut. During the next few days, the spirochetes invade the midgut wall, traverse the hemolymph system, and within a few weeks infect the salivary glands as well as other tick tissues and organs. Females may develop infected ovaries and transmit Borrelia to offspring in some Ornithodoros species, but this is rare in O. hermsii.[20] Having reached the tick's salivary glands, the spirochetes are poised to invade the tick's next host.

TICK BEHAVIOR

In contrast to the hard-bodied ticks, these soft ticks feed rapidly, often detaching after 30 to 90 minutes.[20,21] They feed at night while people are sleeping, and their bite is usually painless. Therefore, most people are unaware that they have been bitten.[18]

Disease Characterization

The hallmark of endemic relapsing fever is an abrupt onset of high fever (often >39°C) after an incubation period of 4 to 18 days.[20] The patient may experience shaking chills, severe headache, abdominal pain, myalgias, arthralgias, nausea, vomiting, and malaise. A few cases of acute respiratory distress syndrome have recently been recognized.[20] The fever usually breaks in 3 days (range, 12 hours to 17 days) in untreated patients.[20] After a variable afebrile period of 3 to 36 days (usually 7 days), cyclic periods of fever and constitutional symptoms reappear. Each febrile attack progressively diminishes in severity. Three to five relapses typically occur in untreated patients.

Routine laboratory testing is of little value. Moderate anemia and an increased erythrocyte sedimentation rate (ESR) are common. Leukocyte counts may be normal, yet moderate-to-severe thrombocytopenia is commonly observed but is considered nonspecific. The diagnosis of relapsing fever is made by direct observation of the spirochete on a peripheral blood smear while the patient is febrile.[20] Observation of the smear is enhanced with Wright or Giemsa staining. Few diagnostic laboratories perform antibody serology tests; however, these tests lack specificity.[20] Skin biopsy of a rash to identify the spirochete is unreliable. Direct culture of the spirochete from the blood into a special culture medium is the most specific diagnostic tool, but this is a slow technique confined to research laboratories.

TREATMENT

These Borrelia have not demonstrated antibiotic resistance. Successful treatment regimens usually include a 7- to 10-day course of antibiotics.[5,20] Tetracycline (500 mg every 6 hours for 10 days) is the preferred regimen. Erythromycin is an effective alternative at a dose of 500 mg (or 12.5 mg/kg) every 6 hours for 10 days. For individuals experiencing central nervous system (CNS) involvement, ceftriaxone (2 g/day for 10–14 days) is preferred. Hospitalization and administration of IV antibiotics may be required in severely ill patients.

CASE 82-6

QUESTION 1: T.J. is a 49-year-old man who visits his PCP with a sudden onset of high fever, severe headache, malaise, nausea, vomiting, and myalgias. He returned a week ago, at the end of August, from a stay in a rustic cabin on the north rim of the Grand Canyon. His PCP orders a manual complete blood count (CBC) and chemistry panel and asks the laboratory to observe a blood smear with Giemsa staining. T.J.'s recent visit and outdoor activities are consistent with areas with prior outbreaks where relapsing fever has been documented. After confirming the presence of Borrelia in the blood smear, the PCP prescribes a 10-day course of tetracycline. Two hours after the first dose, T.J.'s wife calls the physician's office with concerns that the disease is worsening. T.J. experiences an increased temperature, faintness, and chills, and has a rapid pulse and respiration rate. What do these symptoms represent? Is this an adverse drug reaction?

Up to 54% of patients with relapsing fever experience a reaction, a Jarisch–Herxheimer reaction, to the first dose of antibiotic (see Chapter 72 Sexually

Transmitted Diseases).[21] It may occur in LBRF, TBRF, and in other spirochetal diseases such as syphilis or Lyme disease.[3] The dramatic reaction consists of a rise in temperature, chills, myalgias, tachycardia, hypotension, increased respiratory rate, and vasodilation.[20] Treatment of the reaction consists of supportive care. Severe reactions may require hospitalization for vital sign monitoring and management of hypovolemia. Although this is a reaction to the administration of an antibiotic drug, it is not an allergic response, and the antibiotic should be continued.

BORRELIA MIYAMOTOI

CASE 82-6, QUESTION 2: T.J. continues with antibiotic therapy and his symptom resolves. Given his clinical presentation and findings, his diagnosis and treatment were appropriate. How does Borrelia miyamotoi typically present and what treatment options are available?

Borrelia miyamotoi is a bacterial species that is closely related to the bacteria that cause TBRF and distantly related to Borrelia burgdorferi that causes Lyme disease. While first identified in 1995 in ticks from Japan, B. miyamotoi has been detected in two species of North American ticks, the black-legged or deer tick (I. scapularis) and the western black-legged tick (I. pacificus). The first human cases of infection were identified in Russia and described in 2011, followed by the first recognized cases in northeastern United States in 2013.[22] To date, there are less than 60 well-documented cases of B. miyamotoi in the United States. Because ticks are also known to transmit several diseases, including Lyme disease, anaplasmosis, and babesiosis, researchers and healthcare providers need to learn more about the transmission and signs and symptoms of this infection.

Patients with B. miyamotoi infection generally experience nonspecific symptoms such as fever, chills, headache, myalgia, and arthralgia.[22,23] Unlike Lyme diseases, rash was an uncommon finding, with only 4 out of 51 patients experiencing a rash. The blood tests that are used for Lyme disease are not helpful in the diagnosis of B. miyamotoi infections. Currently, the PCR tests that detect DNA from the organism or antibody-based tests are used for confirmatory diagnosis. Patients with B. miyamotoi have been successfully treated with a 2 to 4 week of doxycycline, and amoxicillin and ceftriaxone have also been used. Borrelia miyamotoi disease will continue to be evaluated, and it may be an emerging tick-borne infection in the northeastern region of the United States.

SOUTHERN TICK-ASSOCIATED RASH ILLNESS (STARI)

CASE 82-7

QUESTION 1: G.T., a 47-year-old man living in southern Missouri, recently experienced a rash resembling EM after a lone star tick bite. Because this tick is not a vector for Lyme disease, what could be the cause and how should he be managed?

Amblyomma americanum (the lone star tick) is found throughout the southeast and south-central US and along the Atlantic coast as far north as Maine, and its territory is expanding.[4] The lone star tick aggressively bites humans in the southern states, as opposed to I. scapularis ticks.[5,24] Spirochetes detected by microscopy and culture have been found in 1% to 5% of lone star ticks and are named Borrelia lonestari.[2,5,24] B. lonestari and B. burgdorferi, however, were ruled out as the cause of EM -like skin lesions known as STARI in one Missouri investigation.[5,24] Attempts to culture the agent of this Lyme-like illness, although exhaustive, have been unsuccessful.[24] The causative agent of STARI has not yet been confirmed. There are differences in the appearance and content of the rashes of STARI and the EM of Lyme disease. For example, Lyme EM rashes show an abundance of plasma cells contrasted with a predominantly lymphocytic infiltrate seen in STARI.[24]

G.T.'s diagnosis was based on symptoms, geographic location, and tick bite information. Because the cause of STARI is unknown, no diagnostic tests are available, nor is it known if antibiotic treatment is necessary or beneficial for patients. However, because STARI resembles Lyme disease, limited data support treating STARI with regimens similar to those used for Lyme disease.[24] For example, doxycycline may be given for 10 to 30 days, with longer durations reserved for evidence of dissemination beyond the rash, such as fever, severe headache, lymphadenopathy, or multiple rashes.[25]

OTHER BACTERIAL DISEASES: TULAREMIA

Tularemia

ETIOLOGY AND EPIDEMIOLOGY

In 1911, George W. McCoy and Charles W. Chapin from the US Public Health Service investigated a plague-like disease in wild ground squirrels harvested in Tulare County, California, and discovered the infectious etiology of tularemia.[25] The bacterium is a small, pleomorphic, catalase-positive, nonmotile, aerobic, nonencapsulated, gram-negative coccobacillus now named Francisella tularensis in honor of Edward Francis for his fieldwork and contributions to tularemia research. He proposed the terminology tularemia because the disease is associated with bacteremia.[25]

Although tularemia is found worldwide, it occurs primarily in the Northern Hemisphere.[22] The important reservoir hosts for F. tularensis are wild rabbits, ticks, and deer flies.[25] The North American tick vectors are Dermacentor variabilis (dog tick), Amblyomma americanum (lone star tick), and Dermacentor andersoni (wood tick). Tick-borne tularemia occurs most often in the spring and summer, matching the likelihood of exposure.[4] Before 1950, most human cases of the disease developed from direct contact with infected animals, usually hares or rabbits, and tularemia cases that occurred in the fall or winter were usually associated with hunting season exposure. Tick bite transmission, however, now accounts for more than half of tularemia cases west of the Mississippi River in the United States. In summer months, tick or fly bites appear to be the main mode of transmission of tularemia to humans. Other animals, such as domestic cats, are susceptible to tularemia and are known to have transmitted tularemia to humans.[4] Tularemia outbreaks have also occurred among hamsters purchased from pet shops. Individuals should be careful when handling any sick or dead animal. Other modes of transmission include ingestion of, or contact with, infected meat, water, or soil; inhalation of aerosolized bacteria; or bites from infected animals, mosquitoes, or deerflies.[25] Direct person-to-person transmission has not been reported.

CLINICAL PRESENTATION

The clinical manifestations of tularemia are related to the mode of transmission, patient characteristics, and bacterial subspecies causing infection.[25] Classically, six types of tularemia presentation have been identified: ulceroglandular, glandular, typhoidal, oculoglandular, oropharyngeal, and pneumonic. The last three forms were presumably not tick-borne, reflecting alternative avenues of transmission. Today, the clinical manifestations fall into two main groups: ulceroglandular and typhoidal.[25]

Ulceroglandular is the most common form of tularemia, accounting for approximately 75% of cases.[25] Sixty percent of ulceroglandular cases are characterized by an ulcer that forms at the site of entry, usually on the lower extremities, perineum, buttocks, or trunk from arthropods that tend to bite the lower extremities or on the upper extremities from mammalian bites.[22] The lesion starts as a firm, erythematous papule that ulcerates and heals over the course of several weeks. It is accompanied by regional, painful lymphadenopathy, usually inguinal or femoral. Typhoidal tularemia, occurring in approximately 25% of cases, is characterized by fever, chills, headache, debilitation, abdominal pain, and prostration. Fever and chills are common with all forms of tularemia.[25]

After exposure to the bacteria and an incubation period of 4 to 5 days, patients become ill with a sudden onset of fever, chills, headache, cough, arthralgias, myalgias, fatigue, and malaise. The severity of symptoms is quite variable, ranging from a mild, limited disease (probably type B tularemia) to rare cases of septic shock (probably type A tularemia). A hallmark manifestation is a high fever without an accompanying increase in pulse, or pulse–temperature disparity.[22] Common complications are mild hepatitis, secondary pneumonia, and pharyngitis. With antibiotic treatment of uncomplicated tularemia, mortality rates are only 1% to 3%. Increased morbidity and mortality are seen in the more rare typhoidal forms.[25] The most lethal form of tularemia is from pulmonary infection.[25] In the healthcare setting, standard precautions are all that is required when caring for tularemia-infected patients because they are not a source for secondary infection. However, any suspected outbreaks should be reported and investigated.[25]

DIAGNOSIS

Tularemia can be difficult to diagnose as routine laboratory testing is of little help in establishing a diagnosis and is limited to the demonstration of an antibody response to the bacteria. Because an antibody response to the illness requires 10 to 14 days for detection, treatment is usually empiric. The diagnosis is based on clinical suspicion from the epidemiologic history and the presence of compatible findings. The customary serologic test demonstrates F. tularensis antibody agglutination. Although a single-tube agglutination test with a titer of 1:160 or more (or 1:128 or more using a microagglutination study) in a suspected case is highly suggestive of a tularemia diagnosis, a fourfold or greater rise in titers between the acute and convalescent stages 2 weeks apart is diagnostic.[26] After a bout of tularemia, detectable antibodies may persist for many years.[25]

TREATMENT

Antibiotic treatment options for tularemia have included streptomycin, gentamicin, doxycycline, and ciprofloxacin. Streptomycin was historically the drug of choice for tularemia, but it is often unavailable commercially. Some clinicians believe that gentamicin is the best alternative aminoglycoside for the treatment of nonmeningitic tularemia. Its advantages compared with streptomycin include lower minimal inhibitory concentrations (MICs), less vestibular toxicity, and wider commercial availability. Although considered comparable in efficacy to streptomycin, gentamicin has been associated with increased treatment failure and relapse. Tobramycin is inferior to gentamicin or streptomycin and should not be used.

In many of the reported studies of antimicrobial therapy for tularemia, short courses of treatment were used. To prevent tularemia from worsening or relapsing, longer regimens (10–14 days) should be used, especially in more severe cases. Jarisch–Herxheimer reactions can occur with antibiotic treatment of tularemia. Antibiotic prophylaxis for people exposed to those with tularemia is not recommended, but prophylactic antibiotics might be used for suspected bioterrorism attacks of tularemia. Acute febrile illness with pneumonia and other signs of infection occur 3 to 5 days after exposure to airborne tularemia organisms from an intentionally set weapon. No tularemia vaccines are available in the United States. A partially protective one was developed in the former Soviet Union but was only used for at-risk personnel such as for certain laboratory workers.[23] Personal protective measures, as discussed for Lyme disease, should be used when spending time outdoors in endemic areas.[25]

THE RICKETTSIA: ROCKY MOUNTAIN SPOTTED FEVER, RICKETTSIA PARKERI INFECTION, EHRLICHIOSIS, AND ANAPLASMOSIS

Rocky Mountain Spotted Fever (RMSF)

Rocky Mountain spotted fever is the most prevalent and virulent rickettsial disease in the United States. As early as 1872, RMSF infected white settlers of the Northwest and it may have been prevalent in Native Americans of the region before that time. It was first described in residents of the Bitterroot, Snake, and Boise river valleys of Montana and Idaho in the late 1800s. Howard Ricketts discovered the causative agent, Rickettsia rickettsii, in 1908.[26] The rickettsia is a small (0.3 × 1 µm), pleomorphic, weakly gram-negative, obligate intracellular coccobacillus that can survive only briefly outside of a host.[26]

EPIDEMIOLOGY

RMSF is found throughout North America, including the United States, Canada, and Mexico, and in parts of Central and South America.[26] It has not been documented outside of the Western Hemisphere. The term "Rocky Mountain spotted fever" is actually a misnomer because the disease has shifted eastward from the Rocky Mountain states, and the greatest incidence of RMSF now occurs in North and South Carolina, Virginia, Oklahoma, Arkansas, and Tennessee.[26,27] Most RMSF infections arise from tick exposure in rural or suburban locations, although rare outbreaks in urban environments have occurred.

The prevalence of RMSF is highest in children with 5 to 9 years of age.[28] Another peak prevalence is seen in men older than 60 years. Risk factors include male sex, residence in wooded areas, and exposure to tick-infected dogs. RMSF, like other tick-borne diseases, is highly seasonal, with greatest incidence in late spring and early summer.[26]

TICK VECTORS AND HOSTS

In the east, south, and west coasts of the United States, the tick vector for RMSF has been identified as the dog tick, Dermacentor variabilis.[2] In the Rocky Mountain states, the wood tick, D. andersoni, is the vector.[24] In Mexico, the tick vectors are Rhipicephalus sanguineus and Amblyomma cajennense, with the latter also being responsible in Central and South America.[24] The brown dog tick, R. sanguineus, has been identified as a new tick vector for RMSF in a defined area of Arizona.[26–28]

Dermacentor ticks feed on humans only during their adult stage.[26] Larval Dermacentor ticks may be infected while feeding on small mammals that have sufficient rickettsemia for transmission, such as chipmunks, ground squirrels, cotton rats, snowshoe hares, and meadow voles. Dogs are not considered reservoirs for R. rickettsii but are susceptible to RMSF and may introduce infected ticks into households.[26,27] Adult ticks transmit the rickettsia transovarially to their progeny with high efficiency and establish newly infected tick lines. If the rickettsia burden is large in the adult tick, however, it may cause tick death, thereby reducing infected tick lines. Therefore, there must be nontick reservoirs, as mentioned previously, to develop newly infected tick generational lines; otherwise, RMSF would slowly disappear. In summary, ticks are both vectors and hosts for R. rickettsii.[26] Humans are dead-end accidental hosts of R. rickettsii.[26]

DISEASE COURSE, SYMPTOMS, AND FATALITIES

Rickettsia rickettsii is usually transmitted to humans from an infected tick bite.[26] The organism can also gain access to humans through broken skin if an infected tick is being crushed with bare fingers, and such crushing may generate infectious aerosols that might be inhaled. Conjunctival contact with infected tick tissues or feces provides another route for rickettsial entry. Contaminated blood transfusions and needle stick injuries have also transmitted R. rickettsii.[26]

After introduction of the organisms into the body, the rickettsia spread hematogenously with a predilection for the vascular endothelium, especially in capillaries and medium-sized blood vessels.[27] During an incubation period of 2 to 14 days, induced phagocytosis allows rickettsial entry into endothelial cells, where they replicate by binary fission in the cytoplasm and nuclei of infected cells. This induces a generalized vasculitis leading to activation of clotting factors, capillary leakage, and microinfarctions in various organs.[26] Exotoxins are not secreted by rickettsia; however, they do induce oxidative and peroxidative damage to host cell membranes, resulting in necrosis.[26] In severe infections, hypotension and intravascular coagulation may coexist and culminate in cell, tissue, or organ destruction.

Dehydration is an early sign of RMSF, followed by increased vascular permeability, edema, decreased plasma volume, hypoproteinemia, reduced serum oncotic pressure, and prerenal azotemia. RMSF is a multisystem disease, but a particular organ may be the

---

major focus of the disease. If the brain or lungs are severely infected, death can ensue. An increased severity of illness is associated with edema, particularly in children, and hypoalbuminemia. Hypotension is present in 17% of patients and hyponatremia in 56%. Extensive infection of the pulmonary microvascular endothelium can cause noncardiogenic pulmonary edema.

A common finding in RMSF is myalgia (72%–83%) or muscular tenderness, which are manifestations of skeletal muscle necrosis. Striking creatinine kinase elevations have been described. Thrombocytopenia resulting from consumption of platelets during intravascular coagulation processes occurs in 35% to 52% of patients. True disseminated intravascular coagulation with attendant hypofibrinogenemia is exceptional, however, even in severe or fatal cases.[27] Blood loss or hemolysis in some may cause anemia, which is seen in 30% of patients and reflects blood vessel damage. Fatalities usually occur 8 to 15 days after illness onset if no treatment is given or is delayed. Long-term sequelae from severe forms of RMSF can include partial paralysis of the lower extremities, gangrene of extremities requiring amputation, deafness or hearing loss, incontinence, and movement or speech disorders, but these occur in a minority of patients who receive prompt antibiotic therapy.[26]

"Fulminant" RMSF is best defined as a disease with a rapidly fatal course with death occurring in approximately 5 days. This form of disease is characterized by an early onset of neurologic signs and late or absent skin rash; it is highly associated with glucose-6-phosphate dehydrogenase deficiency, advanced age, male sex, and possibly heavy alcohol use.[26,27] In the pre-antibiotic era, RMSF mortality rates were as high as 30%, but they have fallen to 5% in antibiotic-treated cases today.[2,27]

The classically defined triad of RMSF symptoms at initial presentation is fever, rash, and headache, but this is found in only up to 5% of cases during the first 3 days of illness and up to approximately 60% of cases 2 weeks after exposure.[26,28] The RMSF skin rash typically begins 2 to 4 days after fever onset as pink, 1- to 5-mm blanchable macules that later become papules.[27] It begins on the ankles, wrists, and forearms, and soon thereafter involves the palms or soles. It then spreads to the arms, thighs, and trunk, and typically evolves into a petechial exanthem. The utility of these findings in the differential diagnosis is limited because rash may be absent, transient, or late; it may never become petechial, or it may have an unusual distribution.

DIAGNOSIS

As for most tick-borne diseases, confirmatory serologic analysis is not particularly useful in early diagnosis of disease. The initial diagnosis is made based on clinical signs and symptoms and medical history. Because RMSF can be a severe or even fatal illness, antirickettsial treatment should begin immediately to prevent morbidity and mortality.[26,27] R. rickettsii is difficult to culture. Immunohistologic demonstration of R. rickettsii in biopsy specimens of rash lesions is the only approach that can yield diagnostic results in a timely manner, but this approach is applicable only to those presenting with a skin rash, and these tests are not readily available.[26]

The best serologic test for RMSF is the indirect immunofluorescence assay (IFA) test, but antibodies typically appear only after 10 to 14 days.[26] More striking laboratory abnormalities of RMSF disease include a normal leukocyte count with a shift to the left, hyponatremia, thrombocytopenia, elevated serum transaminases or creatinine kinase, and CSF pleocytosis. These findings are observed late in the disease course, however, and are not helpful in early disease recognition.

Clinical findings and history are essential to early diagnosis and successful treatment. Therapy must precede laboratory confirmation of RMSF.[26] In a febrile, tick-exposed person with a rash, RMSF should be considered. RMSF should be strongly considered in febrile children, adolescents, or men older than 60 years of age, especially if they reside in or have traveled to the southern Atlantic or south-central US from May through September. A delay in treatment for RMSF beyond 5 days of symptom onset increases the mortality rates from 5% to 22%.

TREATMENT

Doxycycline should be initiated immediately as first-line treatment for RMSF in both adults and children whenever RMSF is suspected. The recommended treatment is doxycycline 100 mg every 12 hours for children under 45 kg (100 lbs): 2.2 mg/kg body weight given twice a day. The standard duration of treatment is 7 to 14 days, including at least 3 days after the temperature has normalized.[4,5] The use of doxycycline to treat suspected RMSF in children is standard practice by the CDC and the American Academy of Pediatrics (AAP) Committee on Infectious Diseases as the use of alternative antibiotics increases the risk of death. Contraindications to doxycycline use include history of severe hypersensitivity reactions to tetracyclines, and in some pregnant patients in which the case of RMSF seems mild, chloramphenicol may be considered as an alternative antibiotic.[26] However, oral formulations of chloramphenicol are not available in the United States, and there are severe risks of adverse of effects with this agent, including gray baby syndrome and aplastic anemia.[26] The erythromycins, penicillins, sulfonamides, aminoglycosides, and cephalosporins are not effective for RMSF, and sulfa drugs may worsen infection.

A crucial component in the management of RMSF is appropriate supportive care.[4] Those with severe disease should be hospitalized and managed with hemodynamic, renal, pulmonary, and fluid support as needed.[4]

PREVENTION

In addition to the same guidelines for prevention of Lyme disease, keeping pets free of ticks can reduce exposure. Ticks must not be crushed in a way that might introduce rickettsia into cutaneous lesions, mucous membranes, or the conjunctiva. No RMSF vaccine is available.[26] Antirickettsial antibiotic prophylaxis after a tick bite is not warranted as there is no evidence that this approach is effective and it may delay the onset of the disease.

Spotted Fever Group Rickettsia (SFGR)

In addition to Rickettsia rickettsii, the agent of RMSF, many other rickettsial pathogens have been recognized and grouped broadly as “Spotted Fever group Rickettsia (SFGR).”[29] In the United States, these pathogens include Rickettsia parkeri and Rickettsia 364D, and internationally, there is a growing number of tick-borne SFGR that are pathogenic to humans.[4,30] Doxycycline treatment is effective and is the antibiotic of choice for tick-borne SFGR infections.[4]

Ehrlichiosis and Anaplasmosis

SPECIES IDENTIFICATION, TICK VECTORS, AND DISEASE HOSTS

Though ehrlichiosis and anaplasmosis are transmitted by two different species of ticks and generally occur in different regions of the United States, patients may have a similar clinical presentation.[4,5] The term “ehrlichiosis” may be more broadly applied to different infections, including Ehrlichia chaffeensis and Ehrlichia ewingii, which are transmitted by the lone star tick generally in the southeastern and south-central US, from the eastern seaboard extending westward to Texas. A third species, provisionally called Ehrlichia muris-like (EML), was identified among patients in the upper Midwest; however, the tick responsible for transmitting

---

EML is unknown and the clinical presentation is undifferentiated from other Ehrlichia species.

Anaplasmosis is a bacterial disease, caused by Anaplasma phagocytophilum, which was first recognized as a disease in humans in 1994.[4] Though previously known as human granulocytic ehrlichiosis (HGE), a taxonomic change in 2001 identified that this organism belongs to the genus Anaplasma and resulted in the name change to human granulocytic anaplasmosis (HGA). To date, the highest incidence of HGA in the United States is reported in the upper Midwest and northeastern states with transmission by the black-legged tick (Ixodes scapularis). Along the West Coast, it is transmitted by the western black-legged tick (I. pacificus).

CLINICAL AND LABORATORY FINDINGS

Human ehrlichiosis and anaplasmosis usually present as nonspecific, febrile, flu-like illnesses resembling RMSF. The symptoms caused by infection generally develop 1 to 2 weeks following the bite of an infected tick and are variable. Patients who are immunocompromised (e.g., receiving corticosteroids, cancer chemotherapy, long-term immunosuppressive therapy following organ transplant), or who have HIV infection or splenectomy may experience more severe disease and greater risk of mortality.

The following signs often are noted: hypertransaminemia, leukopenia (often with a shift to the left), and thrombocytopenia. A skin rash is an uncommon feature of ehrlichiosis and is rarely seen with anaplasmosis. However, up to 60% of children can experience a rash caused by Ehrlichia chaffeensis. The diagnosis of ehrlichiosis and anaplasmosis must be made based on clinical findings, as treatment should never be delayed pending the results of confirmatory laboratory testing or be withheld on the basis of an initial negative laboratory result. In patients presenting with known tick exposure, fever, thrombocytopenia, and increased liver function test, a peripheral smear should be performed. A peripheral blood smear showing neutrophilic morulae supports a provisional diagnosis, though this characteristic finding is not present in most cases. Confirmatory testing by serology or PCR or direct culture is still required to establish a diagnosis.[31] As with many other tick-borne diseases, serologic findings of antibody response to ehrlichiosis or anaplasmosis assist only by retrospectively confirming the diagnosis.

TREATMENT AND PREVENTION

CASE 82-8

QUESTION 1: G.C., a 68-year-old man living in northwest Wisconsin, presents with an influenza-like illness in late May. He has a two-day history of fever, shaking chills, headache, myalgias, nausea, and anorexia. On examination, his temperature is 39.4°C, but other physical findings are unremarkable. No skin rashes are found. G.C. states that he had multiple tick bites 1 week ago while he was fur trapping. The physician suspects anaplasmosis. Blood is drawn for serology, CBC with differential, chemistry profile, and a Wright stain microscopic examination. Immediately available abnormal results include neutrophilic morulae on microscopy, a WBC count of 2,500/μL, a platelet count of $80 \times 10^3/\mu L$, C-reactive protein of 136 mg/L (normal, 4–8 mg/L), aspartate aminotransferase (AST) of 150 IU/L, and lactate dehydrogenase of 700 IU/L. Serology is still pending. What antibiotic treatment should be initiated?

G.C.'s history is significant for HGA. He was in the right place, the upper Midwestern US, and was outdoors during the right season; most patients are diagnosed with HGA in May through August, and his history fall within the usual 1- to 2-week incubation period from tick bite to onset of illness.

His symptoms are also important. Nearly 100% of patients with HGA have a fever of greater than 37.6°C. Other symptoms in G.C. consistent with HGA are rigors (shaking chills), headache, myalgias, nausea, and anorexia. Matching laboratory findings include neutrophilic morulae. The laboratory findings of leukopenia and thrombocytopenia strongly support the diagnosis of anaplasmosis. Evidence of mild-to-moderate hepatic injury, as seen by the elevated liver enzyme results, is helpful in HGA diagnosis.

Doxycycline is the first-line treatment for G.C. and should be used for both adults and children of all ages whenever anaplasmosis or ehrlichiosis is suspected.[4,5] In patients such as G.C. who are treated within the first 5 days of the disease, a good response to doxycycline occurs with fever resolution generally in 2 days.[32] Fever persisting for more than 2 days after doxycycline treatment suggests that the diagnosis is incorrect.

THE PROTOZOA: BABESIOSIS

Babesia, Ticks, and Hosts

There are more than 100 species of Babesia having a worldwide geographic range.[4] However, only relatively few species have caused documented cases of human infection, including B. microti, B. divergens, B. duncani, and currently an unnamed agent designated MO1.[4,32] The most common cause of human babesiosis is B. microti, which is transmitted by Ixodes scapularis ticks, primarily in the endemic regions in the Northeast and upper Midwest of the United States; however, sporadic cases of babesiosis have occurred in other regions, including the West Coast. In addition to the Ixodes ticks, Babesia species are also transmitted by Dermacentor, Haemaphysalis, and Rhipicephalus ticks. Because B. microti is typically transmitted by the nymphal stage of I. scapularis tick (about the size of a poppy seed), infected patients may not recall a tick bite.

SYMPTOMS AND DIAGNOSIS

CASE 82-9

QUESTION 1: H.W., age 68 years, lives in Martha’s Vineyard in Massachusetts. During the month of July he enjoyed a day of boating, fishing and hiking at a nearby lake. About a week later, he felt fatigued and lost his appetite. He presents to his local PCP in the middle of August with complaints of fever, headache, drenching sweats, aches and pains, and occasional dark-colored urine. He does not recall a tick bite. On physical examination, he has splenomegaly and hepatomegaly. Laboratory tests show a severe normochromic, normocytic anemia, decreased hemoglobin, hemoglobinuria, thrombocytopenia, and increased liver enzymes. His temperature is 40°C. Examination of a Giemsa-stained thin blood smear reveals the presence of unpigmented ring-shaped intraerythrocytic parasites in more than 5% of his erythrocytes. The PCP institutes an atovaquone plus azithromycin regimen. What was the clue to the diagnosis of babesiosis?

The diagnosis of babesiosis was confirmed by the direct observation of the protozoan inside the red blood cells. Although the Giemsa-stain test is a commonly used tool, it is subject to false-negative results because the rate of parasitemia is typically low. Usually, multiple blood smears need to be examined because less than 1% of erythrocytes may be infected early in the course of the disease when most people seek medical help.[3,32] Because blood smear inspection is often not successful in diagnosing babesiosis or may only detect a few parasites, additional supportive laboratory results are advocated, such as serology using IFA for IgM and IgG antibabesial antibodies or PCR detection of babesial DNA in the blood.[3]

The clinical findings in patients with babesiosis are similar to those of malaria, ranging in severity from asymptomatic to severe complications and death.[11] Most patients with B. microti babesiosis are asymptomatic, though some people may develop nonspecific flu-like symptoms, such as fever, chills, sweats, headache, myalgias, and nausea. This form of babesiosis can be viewed as a distinct, occult, asymptomatic disease with few known sequelae.[32] A number of transfusion-acquired infections have been documented, reflecting the existence of an asymptomatic form of babesiosis in blood donors.

A second form of babesiosis has been termed a "mild-to-moderate viral-like illness."[33] It has a gradual onset of fatigue and malaise and later fever accompanied by one or more of these symptoms: chills, sweats, headache, arthralgias or myalgias, anorexia, or cough.[30] Rash is rare. It can last weeks to months, sometimes with a prolonged recovery time of up to a year or more.[33]

A third form of babesiosis is a potentially life-threatening hemolytic one that occurs in people predisposed to severe infection because of advanced age, immune suppression as a result of HIV disease or immunosuppressants, malignancy, or prior splenectomy.[32] Although babesial infection is as prevalent in children as it is in adults, it is more severe in adults older than 50 years of age. Complications seen in severe babesiosis include acute respiratory failure, disseminated intravascular coagulation, congestive heart failure, coma, and renal failure, with a 5% to 9% mortality rate.[3,32]

In the northeastern US, infections commonly occur in patients with spleens, as in H.W. Clinically apparent cases are most common in 50- to 60-year-old patients, many of whom do not recall a tick bite. Most symptoms of babesiosis are caused by hemolysis or the systemic inflammatory responses to parasitemia.[30] The usual incubation period is 1 to 6 weeks after a tick bite based on limited data.[34] Nonspecific, viral-like symptoms that are gradual in onset appear first, as in H.W.'s case, followed several days later by the other symptoms H.W. displayed. A hallmark of the disease is hemolytic anemia of varying severity. A high index of suspicion for babesiosis should be maintained in any patient with an unexplained febrile illness who lives in or has traveled to a region where the infection is endemic during June through August, as in H.W.'s case, particularly if there is a history of tick bite.

TREATMENT

CASE 82-9, QUESTION 2: Is atovaquone and azithromycin an appropriate treatment regimen for H.W.? What other drugs have been used?

The discovery of an original human babesiosis treatment regimen combining clindamycin and quinine was a fortuitous one. In 1982, an 8-week-old infant with presumed transfusion-acquired malaria was initially treated with chloroquine.

Because of a lack of response, treatment was switched to quinine plus clindamycin, and the patient's fever decreased. A correct diagnosis of babesiosis was subsequently confirmed. Although this treatment combination is still used, frequent side effects (e.g., tinnitus, vertigo, and diarrhea) occur, often resulting in dose reduction or discontinuation.[3,32] Treatment failures with this regimen have occurred in splenectomized patients, patients with HIV infection, or those receiving concurrent corticosteroids.[3]

For mild-to-moderate babesiosis, atovaquone plus azithromycin is the regimen of choice, as H.W. received. This regimen has also achieved cures in pediatric cases, although a controlled trial study has not been performed.[32] On the other hand, persistent relapsing babesiosis and emergence of resistance have occurred in immunocompromised patients receiving this regimen.[33,35] It has been suggested that the usual 7- to 10-day course treatment regimen may not be adequate in these patients.[35] Combination therapy of azithromycin with atovaquone is better tolerated than clindamycin–quinine combinations. The dosing is atovaquone 750 mg orally every 12 hours and azithromycin 500 mg to 1,000 mg orally on day 1 and 250 mg to 1,000 mg on subsequent days for 7 to 10 days.[32] Increased azithromycin doses of 600 mg to 1,000 mg/day may be used in immunocompromised patients.[3,36] Children should receive atovaquone 20 mg/kg (maximum, 750 mg dose) every 12 hours and azithromycin 10 mg/kg (maximum, 500-mg dose) on day 1 and 5 mg/kg (maximum, 250-mg dose) orally thereafter for 7 to 10 days.[3,32]

For severe babesial illness, the intravenous clindamycin plus oral quinine should be given.[32] Dosing recommendations for adults are clindamycin 300 mg to 600 mg IV every 6 hours plus quinine 650 mg orally every 6 to 8 hours for 7 to 10 days; children should receive clindamycin 7 to 10 mg/kg (maximum, 600-mg dose) IV every 6 to 8 hours plus quinine 8 mg/kg (maximum, 650 mg dose) orally every 8 hours for 7 to 10 days.[3,32]

Antimicrobials should be used in all patients with symptomatic, active babesiosis once the diagnosis is confirmed by PCR or blood smear, owing to the risk of disease complications.[34] Antibody-seropositive, symptomatic patients without identifiable parasites on blood smear or PCR positivity should not be treated. Similarly, asymptomatic patients should not be treated regardless of serologic results, blood smear examinations, or PCR findings. A course of treatment should be considered in asymptomatic patients, however, if these tests are positive and repeat testing demonstrates persistent parasitemia for more than 3 months.[3,32]

Partial or complete red blood cell transfusions may be lifesaving in severe babesiosis for patients having high-grade parasitemia (10% or more infected erythrocytes), significant hemolysis, or pulmonary, renal, or hepatic compromise.[3] Rapidly increasing parasitemia leading to massive intravascular hemolysis and renal failure mandates immediate treatment for this form of the disease. Patients receiving antibiotic treatment, in particular those with severe or persistent symptoms, should be evaluated for coinfection with B. burgdorferi or A. phagocytophilum or both.

Babesiosis prevention is the same as for other tick-borne diseases. Asplenic patients should avoid areas where babesiosis is endemic. To date, no supportive data for the use of prophylactic antibiotics to prevent babesial infection after a tick bite are available.[32] Although developed for use in cattle, babesial vaccines are not available for humans.

THE VIRUSES: COLORADO TICK FEVER, TICK-BORNE ENCEPHALITIS, AND OTHER VIRALLY MEDIATED TICK-BORNE DISEASES

Colorado Tick Fever

VIRUS IDENTIFICATION, TICKS, AND HOST RESERVOIRS

“Mountain fever” has been described since the first immigrants arrived in the Rocky Mountains. It was later renamed Colorado tick fever (CTF), and the Colorado tick fever virus (CTFV) was identified as the cause.

CTF is caused by a double-stranded RNA Coltivirus. It is an intraerythrocytic virus. At least 22 strains of CTFV are known, but antigenic variation among human strains is low.[33] The virus is an arbovirus because it replicates inside ticks. The primary nidus

of infection is thought to be CTFV invasion of hematopoietic progenitor erythroblasts, and it remains sheltered in mature erythrocytes.[37,38]

CTF is a viral illness transmitted by the bite of an infected tick.[37] Although at least eight tick species have been found to be infected with the virus, adult D. andersoni ticks are the primary tick vector that transmits CTF to humans.[37,38] D. andersoni feeds on numerous mammals, but ground squirrels, porcupines, and chipmunks are the primary reservoirs for CTFV as well as the ticks themselves.[37,38] Transstadial transmission of CTF virus within the tick ensures it is infected for life.[37]

PREVALENCE

CTF is contracted in forested mountain areas at higher elevations of the western Black Hills and Rocky Mountain regions of the United States and Canada, especially on the south-facing brush slopes and dry rocky surfaces of mountains east of the Continental Divide.[37,38] Although CTF can develop from March to October, May through July are peak incidence months.[4,5]

SYMPTOMS

CASE 82-10

QUESTION 1: T.P., a previously healthy 27-year-old native of Atlanta, Georgia, returns from a 1-week late-spring camping trip with her friends in the eastern Colorado Rocky Mountains. Four days later, she experiences fever, chills, headache, myalgias, conjunctivitis, and lethargy. She recalls no tick bites and has no skin rashes. Suspecting RMSF, her physician prescribes doxycycline. T.P.'s symptoms and fever initially resolve, but 2 days later her symptoms return. Physical examination at this time reveals a temperature of 39°C. Routine laboratory tests are normal, although leukopenia is observed with a WBC count of 2,400/μL. Explain how T.P.'s symptoms suggest a diagnosis of CTF?

Symptoms of CTF usually start 3 to 5 days after a tick bite, although more than half of patients do not remember being bitten.[37,38] The most common initial symptoms are fever of rapid onset, headache, chills without true rigors, and myalgias.[37] A rash, which may be petechial, maculopapular, or macular, can occur in 5% to 15% of patients.[38] About half of patients with fever experience a "biphasic" pattern of fever and other symptoms, which means they have several days of fever, then improve for several days, and then have a second period of fever and illness.[37,38] Sequelae are rare, although fatigue and malaise may last for months.[38] One- to three-week periods of convalescence are usual. Children, however, experience complications more frequently than adults. Patients with suspected CTF should defer from donating blood or bone marrow for at least 6 months after their illness because the virus may stay in red blood cells for several months and can be passed to others via blood transfusions.

LABORATORY FINDINGS

Moderate-to-significant leukopenia is the most important finding in CTF. Leukocyte counts are usually normal on the first day, but decrease to 2,000 to 4,000/μL by the fifth or sixth day of illness with a lymphocytic predominance.[38] In one-third of confirmed CTF cases, however, the leukocyte counts remained around 4,500/μL. Counts return to normal within a week of fever abatement in most cases. Thrombocytopenia may occur.[37,38] Although the CSF may show a lymphocytic pleocytosis, this does not distinguish CTF from other causes of meningoencephalitis.[38]

DIAGNOSIS AND TREATMENT

CTF diagnosis can be made serologically, either with IFA staining of erythrocytes, complement fixation, or ELISA.[37,38] The most sensitive isolation system is intracerebral injection of infected blood into suckling mice.[37,38] A reverse transcriptase PCR of specimens can be diagnostic within the first 5 days of illness, whereas serologic tests are more relevant for diagnosis 2 weeks after symptom onset.[38] There is no specific treatment available for patients with CTF infection, which is usually self-limiting. Supportive care should be provided. The best protection for CTF is tick prevention strategies.[38]

TICK-BORNE ENCEPHALITIS (TBE)

Tick-borne encephalitis, a life-threatening neurologic disease, is a growing public health concern in Europe and Asia as the incidence of TBE virus has significantly increased in the past decade.[4,34] TBE virus is divided into three subtypes: Central European (western subtype), Siberian, and Far Eastern (Russian spring–summer or eastern subtype), and is endemic to central and eastern Europe, Russia, and the Far East, with some overlap in geography.[4,34]

The etiologic agents are spherical, lipid-enveloped RNA viruses in the genus Flavivirus.[4,39] The western subtype is transmitted to humans by I. ricinus, and the Siberian and Far Eastern subtypes are transmitted by I. persulcatus, although I. ovatus is the vector in Japan.[40] A minority of TBE cases have followed the consumption of infected unpasteurized milk or cheese directly without a tick vector.[39] The main virus reservoirs are small rodents.[39] Ticks are vectors, and humans are accidental hosts of the virus. Ticks can become infected for life by the virus at larval, nymphal, or adult stages, can acquire it during mating, and can maintain the virus transovarially and transstadially.[39] TBE viruses are transmitted from the saliva of an infected tick very rapidly, within minutes of the bite, so early removal of the tick may not prevent subsequent encephalitis.

As the disease name implies, the ultimate outcome of the infectious process is manifested as CNS involvement, with symptoms of aseptic meningitis, meningoencephalitis, and meningoencephalomyelitis. TBE begins as a febrile headache with progression to CNS manifestations. There is no antiviral treatment available and treatment is supportive, including management of any complications. Two inactivated cell culture-derived preventive human TBE vaccines are available in Europe, in adult and pediatric formulations (FSME-IMMUN and Encepur).[4] The adult formulation of FSME-IMMUN is also licensed in Canada. Two other inactivated TBE vaccines are available in Russia (TBE-Moscow and EncVir). The reader is referred to the CDC for information regarding vaccination to TBE-endemic countries.[4]

POWASSAN DISEASE

Powassan virus infection is an RNA virus belonging to the genus Flavivirus that is related to West Nile, St. Louis encephalitis, and tick-borne encephalitis viruses.[4] Powassan disease is now recognized in the United States, Canada, and Russia. In the United States, approximately 60 cases have been reported in the past decade primarily from northeastern states and the Great Lakes region. The incubation period ranges from 1 week to 1 month. Many people who become infected are asymptomatic. Signs and symptoms of illness can include fever, headache, vomiting, and malaise. Because the Powassan virus can infect the CNS, progression of disease to meningoencephalitis with confusion, seizures, and memory loss may occur. There are currently no vaccines or treatment for Powassan disease. Supportive care should be provided to patients with suspected disease.

THE TOXINS: TICK PARALYSIS

Tick Paralysis

CASE 82-11

QUESTION 1: C.M., a 7-year-old girl residing in Spokane, Washington, complains to her parents that she feels weakness in both legs. The next day, her mother notices that C.M. has worsened and immediately takes her to the pediatrician. The physician finds that C.M has begun experiencing flaccid paralysis in both legs and the lower trunk, although she is alert and oriented. The pediatrician finds that there is a tick attached to C.M.'s scalp under her hair and removes it. C.M. is back to full health in 2 days. What happened?

Tick paralysis (tick toxicosis) occurs worldwide in humans and many animals, and was first described by the explorer Hovell in Australia in 1824.[40] Although 60 tick species worldwide can produce tick paralysis in animals and humans, it is predominantly caused in humans by D. andersoni and D. variabilis in North America.[40] In Australia, Ixodes holocyclus is the culprit.[40]

Most human cases occur during the spring and summer in Australia and North America. In the United States, it is most common in the Pacific Northwest and adjacent areas of southwestern Canada and in the Rocky Mountain states.[40] In children, girls are more commonly affected; however, in adults, more men are affected.[40] Of epidemiologic significance, a young girl's long hair provides camouflage for feeding ticks.[40]

The cause of tick paralysis is the secretion of a neurotoxin present in the large salivary glands of female ticks. They must usually be attached to a host for 4 to 5 days before symptoms develop.[40] The toxin affects motor neurons, decreases acetylcholine release, and may have a mechanistic similarity to botulinum toxin.[40] Paresthesias and symmetric weakness in the lower extremities with motor difficulties progress to an ascending flaccid paralysis in several hours or days. Cerebral sensorium is usually spared, pain is absent, and the blood and CSF are normal.[40] If the tick is not removed, the toxicosis can progress to respiratory paralysis and death.[40] Initially reported mortality rates of 10% have fallen dramatically with our modern intensive care units and available respiratory care.[40] A Washington State case series of 33 patients conducted over the course of 50 years revealed a mortality rate of 6%, with the last two patients' deaths occurring in the 1940s.[40] Children are likely more vulnerable to tick paralysis than adults because the dose of neurotoxin present per kilogram of body weight is higher.[39] Diagnosis should include a complete body examination of the skin for the presence of an engorged tick.[39]

In North America, tick removal commonly results in complete recovery within hours to days. In Australia, the disease is more acute, and paralysis may continue to progress for 2 days after tick removal. Recovery from the disease in Australia may take several weeks. Treatment is supportive. Antitoxin derived from dogs is the treatment of choice for animals, but it also has been used occasionally in humans in Australia with severe tick paralysis.[40] Local experts must determine its use on a case-by-case basis because of the risk of serum sickness or acute allergic reactions.[39]

MIXED INFECTIONS

Because the tick vectors and mammalian hosts are the same for babesiosis, anaplasmosis, and Lyme disease in the northeastern US, all three diseases, theoretically, could be transmitted to a human from one tick bite. Human coinfection by the agents of Lyme disease, babesiosis, or anaplasmosis can occur, especially in endemic areas.[5] Coinfection may alter the natural course for each disease or increase clinical manifestations, especially flu-like symptoms, in concurrent Lyme disease with babesiosis or HGA. Because the same tick vector in Europe and Russia can carry Lyme disease and TBE, dual infection may result in more severe disease.[39]

Dual infection may affect the choice of initial antibiotic therapy. For example, although amoxicillin is sometimes used to treat early Lyme disease, it is not effective for HGA. Doxycycline, however, is useful in both of these diseases. Thus, some cases of Lyme disease that were believed to be treatment failures may actually have been confounded by coinfection. Patients with concurrent Lyme disease and babesiosis have more symptoms and a longer duration of illness compared with patients with single infections. When moderate-to-severe Lyme disease is diagnosed, the possibility of concomitant babesial or anaplasma infection should be considered in regions where both diseases are endemic. Neutropenia and thrombocytopenia are associated with anaplasmosis, anemia and thrombocytopenia are associated with babesiosis, and neither is routinely found in Lyme disease.[5] For patients with Lyme disease who experience a prolonged flu-like illness that fails to respond to appropriate antiborrelial therapy in an endemic area, clinicians should consider testing for babesiosis and anaplasmosis.[5]

SUMMARY

Most of the research into tick-borne human disease demonstrates a close historical relationship of endemic tick-deer-rodent cycles for various microorganisms. Tick-borne diseases have become increasingly challenging and a serious global problem. Scientists continue to search for improvements in diagnosing, treating and preventing tick-borne diseases, as well as controlling the tick populations that transmit microbes. We will continue to encounter increasing cases of tick-borne human disease of known or unknown causes. Because patients present frequently with nonspecific signs and symptoms, a high index of suspicion is crucial to include a tick-borne illness in the differential diagnosis of those presenting with symptoms compatible with a tick-borne illness. It is essential to obtain a careful history of possible tick exposure and consider the epidemiology of infected ticks when considering the possibility of tick-borne illnesses. It is important to increase awareness of personal protection strategies and tick avoidance.

ACKNOWLEDGMENT

Anxiety Disorders

Jolene R. Bostwick and Kristen N. Gardner

CORE PRINCIPLES		CHAPTER CASES
CLINICAL ASSESSMENT AND DIFFERENTIAL DIAGNOSIS		
1	Anxiety disorders are characterized by anxiety that is out of proportion to any actual threat and is excessive for the situation or distressing to the point that it interferes with daily functioning. Both medical and medication-related factors can cause or exacerbate anxiety.	**Case 83-1 (Question 1), Table 83-2**
GENERALIZED ANXIETY DISORDER		
1	Generalized anxiety disorder (GAD) is defined in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, (DSM-5) as a chronic state of waxing and waning anxiety that is associated with an inability to control symptoms of anxiety and worry. The severity of anxiety and the degree of impairment in daily activities are the main determinants of whether medication should be used to treat GAD.	**Case 83-2 (Question 1), Table 83-3**
2	First-line therapies for the treatment of GAD may include medications such as venlafaxine, duloxetine, selective serotonin reuptake inhibitors (SSRIs), buspirone, or benzodiazepines, when a rapid onset is needed. Psychotherapy, such as cognitive behavioral therapy (CBT), can also be used alone or in combination with medications. Specific treatment for GAD should be chosen based on prior therapy, comorbid psychiatric disorders, pharmacokinetic drug properties, desired onset of effect, and patient preference.	**Case 83-2 (Questions 2, 3), Tables 83-4, 83-5, 83-6, 83-8**
3	When beginning treatment with benzodiazepines for GAD, patients should be educated about possible adverse effects, dependence liability, and drug–drug interactions. Possible effects on pregnancy, teratogenicity, and breast-feeding should also be discussed.	**Case 83-2 (Questions 4, 5), Case 83-3 (Question 1), Case 83-4 (Questions 1, 2), Case 83-5 (Question 1), Case 83-6 (Questions 1–3), Table 83-7**
4	Patients beginning treatment with SSRIs, venlafaxine, or duloxetine should be counseled regarding possible adverse effects that may occur early in treatment, as well as those that may occur later and display a more chronic time course. Additionally, all patients being treated with medications for GAD should be counseled regarding the duration of drug therapy.	**Case 83-2 (Question 6)**

PANIC DISORDER

①	Panic disorder is characterized by short episodes of intense fear, associated with perceived physical symptoms such as increased heart rate or respiration, gastrointestinal disturbance, tremor, or feelings of disassociation with the physical body that are often not diagnosed or misdiagnosed because they are attributed by the patient to a medical illness.	**Case 83-7 (Question 1), Table 83-9**
②	Therapy for panic disorder includes CBT, medications (SSRIs, venlafaxine, TCAs, or benzodiazepines), or combination therapy. The expected short-term adverse effects such as jitteriness should prompt using a lower initial medication dose and be discussed with the patient.	**Case 83-7 (Questions 2–4), Table 83-5**

p. 1731

---

p. 1732

SOCIAL ANXIETY AND SPECIFIC PHOBIAS

①	Both social anxiety and specific phobias involve fears that are excessive and lead to avoidance behaviors to minimize fear. Social anxiety involves a generalized and intense anxiety involving social interactions, whereas specific phobias involve intense fear associated with specific objects or situations (e.g., spiders or elevators). SSRIs are first-line treatments for social anxiety, whereas psychotherapy is the primary treatment of specific phobias.	**Case 83-8 (Questions 1–3), Tables 83-5, 83-10**

POST-TRAUMATIC STRESS DISORDER AND ACUTE STRESS DISORDER

①	Post-traumatic stress disorder (PTSD) and acute stress disorder occur in persons who have experienced a severely distressing traumatic event. Re-experiencing symptoms, avoidance, hyperarousal, and negative alterations in cognition and mood cause considerable psychological distress, as well as impairment in occupational functioning and personal relationships in PTSD.	**Case 83-9 (Question 1), Table 83-11**
②	Medications, primarily SSRIs, and CBT are used to treat PTSD. Adjunctive treatment for psychiatric comorbidities such as depression or sleep is often indicated. Treatment goals include reducing the core symptoms of PTSD and improving patient functioning.	**Case 83-9 (Questions 2, 3), Table 83-5**

OBSESSIVE–COMPULSIVE DISORDER

①	Obsessive–compulsive disorder (OCD) is characterized by chronic obsessions and/or compulsions. Obsessions and compulsions can be extremely disabling and usually consume at least an hour a day. OCD can be treated with medications (SSRIs, clomipramine, or venlafaxine), psychotherapy (CBT with or without exposure therapy), or combined modalities for optimal therapy. Despite combination therapy, up to 40% of patients may continue to experience disabling symptoms.	**Case 83-10 (Questions 1–5), Table 83-5**

2 Owing to incomplete remission of symptoms with monotherapy in many patients suffering from OCD, augmentation strategies involving the combination of antidepressants or adjunctive antipsychotics may be considered with vigilant monitoring for increased adverse effects and drug–drug interactions.

Case 83-11 (Questions 1–3)

Anxiety can be described as an uncomfortable feeling of vague fear or apprehension accompanied by characteristic physical sensations. It is a normal reaction to a perceived threat to one's physical or psychological well-being. Anxiety is normally provoked by stress and involves activation of neurobiologic systems that, when activated, contribute to self-preservation. It involves two basic components: mental features (e.g., worry, fear, difficulty concentrating) and physical symptoms (e.g., racing heart, shortness of breath, trembling, pacing). Certain medical illnesses (e.g., pheochromocytoma or hyperthyroidism) and/or medications (e.g., sympathomimetics) can result in both the physical and psychological manifestations of anxiety. However, when the anxiety is attributable to an external cause such as a medical illness or a medication, the anxiety abates when the physiological cause is removed.[1]

If the anxiety is not the result of an external cause, is out of proportion to the actual threat, or persists beyond the presence of the threat, it may be classified as an anxiety disorder. Pathologic anxiety should be differentiated according to whether it occurs (a) as a primary anxiety disorder, (b) as a secondary anxiety disorder owing to medical causes or substances, (c) in response to acute stress (e.g., loss of a loved one, marital or financial problems), or (d) as a symptom associated with other psychiatric disorders to guide optimal treatment.[1]

Classification and Diagnosis of Anxiety Disorders

The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) classifies primary anxiety disorders into seven types: generalized anxiety disorder (GAD), panic disorder, phobic disorders (including specific and social anxiety disorder), separation anxiety disorder, selective mutism, and agoraphobia.[1] Obsessive–compulsive disorder (OCD) and post-traumatic stress disorder (PTSD) are classified under new headings in DSM-5. Each disorder involves an unhealthy level of anxiety, but the characteristic type and severity of symptoms, course of illness, and efficacy of drug and nondrug treatments vary indicating underlying biologic differences. The DSM-5 secondary anxiety disorders include "anxiety disorder due to a general medical condition" and "substance/medication-induced anxiety disorder."[1] Anxiety disorders often present in addition to other psychiatric disorders, such as mood disorders. Both are associated with dysregulations in the limbic system and, therefore, share similar symptoms, including fatigue, impaired concentration, restlessness, difficulties with sleep, and somatic symptoms, although mood disorders have a prominent mood factor.[2]

Neurobiology of Anxiety

The limbic system, which is involved in emotion, learning, and memory, is composed of a set of structures integral to behavior, including the hippocampus and the amygdala. Hippocampal brain circuits are essential for conversion of short-term to long-term memory and for spatial memory, whereas the amygdala circuits are involved with emotion and its expression. A neurocircuit arising from the output pathways of the amygdala is believed to mediate fear and anxiety

responses in humans.[3] Dysregulated or exaggerated output through various amygdala-related circuits may be a common element underlying the different anxiety disorders, but the specific type of dysfunction probably differs among the various disorders. If it is assumed a dysregulation of the stress response is the basis of anxiety disorders, then the genesis of anxiety is probably related primarily to interactions between neural pathways in and between the limbic system structures, the sympathetic nervous system, and the hypothalamic–pituitary–adrenocortical (HPA) axis.[2,4] Many neurotransmitter and neuroendocrine systems interact to modulate the actions of the limbic pathways, including the monoamine neurotransmitters, epinephrine and norepinephrine (NE); corticotrophin-releasing hormone (CRH); the indoleamine, serotonin (5-HT); the inhibitory amino acid, γ-aminobutyric acid (GABA); the excitatory amino acid, glutamate; and the neuropeptides, cholecystokinin (CCK), neuropeptide Y, and substance P.[3,5] As such, the genes from which these products are derived and regulated are an active area of research. Furthermore, epigenetic mechanisms are being investigated to explore the complex relationship between gene–environment interactions.[6]

Interaction of the Hypothalamic–Pituitary–Adrenocortical, Noradrenergic, and Serotonergic Systems

In the event of an acute threat, a fear stimulus is transmitted via the thalamus to the amygdala, which then projects to both the hypothalamus and the brainstem. This results in the peripheral reactions such as increased heart rate and heart stroke volume, and vasodilation of blood vessels carrying blood to the muscles. This is accompanied by a release of NE by the locus coeruleus (LC), the main nidus of NE cell bodies in the brain. Central release of NE results in vigilance, arousal, the ability to focus attention on the threat, and symptoms of anxiety (e.g., tachycardia, tremor, sweating). NE innervation of the hippocampus results in an increased state of memory formation, whereas innervation of the amygdala potentiates the formation of aversive memories.[4] Normally, this is important in allowing us to encode emotionally laden memories, but when overactive, it may result in a constant state of arousal and hypervigilance.

During a perceived threat, CRH is released in the hypothalamus, and it activates the anterior pituitary to release adrenocorticotropic hormone (ACTH). This stimulates the release of glucocorticoid steroids from the adrenal cortex. Although short-term elevation of glucocorticoids allows the body to adapt to a stressful situation by supporting HPA activation and mobilizing energy stores, prolonged elevation of the same glucocorticoids impairs neural plasticity and may even result in neuronal death. When CRH is infused into the LC in rodents, it causes anxiety-like behaviors.[2,4,7]

Although the inhibitory neurotransmitter 5-HT is involved in stress reactions, its role is not entirely clear. Serotonin has roles in sleep, appetite, memory, impulsivity, sexual behavior, mood, motor function, and seems to decrease aggressive behavior. The site of most 5-HT cell bodies in the brain is the raphe nuclei. There is considerable interconnectivity between the raphe nuclei and the LC, and they tend to mutually inhibit one another. Under normal circumstances, 5-HT connections from the hippocampus decrease activity in the amygdala, which would dampen fear and anxiety responses. However, under conditions of stress, the LC accelerates firing, inhibits the raphe nuclei firing, and increases CRH release—all of which sensitize the limbic system and cause arousal and sensitivity to memory of any stressful or aversive stimuli. This primes the system to a state of arousal to deal with the threat.[2]

Although the specific etiology of anxiety is only hypothesized, the current use of treatments activating the 5-HT system, or other inhibitory systems such as the GABA system, supports the hypothesis.

Epidemiology and Clinical Significance of Anxiety Disorders

As a group, anxiety disorders are the most common psychiatric illnesses. Epidemiologic surveys indicate 13% to 28% of Americans suffer from an anxiety disorder at some time in their lives, with similar prevalences in other parts of the world.[8,9] Anxiety disorders are more common in women than in men.[9]

Today, most anxiety disorders can be successfully treated with medications, cognitive or behavioral therapies, or combinations thereof. However, less than one-third of those affected seek help, and many who do are not properly diagnosed.[9] Most medical care for anxiety disorders is rendered in nonpsychiatric settings. Patients commonly present to primary-care providers complaining of physical symptoms that cannot be medically explained, leading to progression of the anxiety disorder. A significant portion of patients with anxiety does not believe in taking medication for emotional problems; others remain untreated because of an inappropriate diagnosis.[10]

Because anxiety is a feeling with which everyone is familiar, there is a tendency to trivialize the impact it can have on a sufferer's functioning and quality of life. An increased understanding about pathologic anxiety is needed in society and healthcare professionals, in particular, so that people seek and receive appropriate treatment. A list of consumer and professional resources for information about anxiety disorders and treatment can be found in Table 83-1.

Clinical Assessment and Differential Diagnosis of Anxiety

CASE 83-1

QUESTION 1: R.R., a 49-year-old woman, complains to her physician of having trouble sleeping, feeling tired and nervous, and worrying constantly. R.R. was divorced 2 years ago, and she retained custody of their 15-year-old daughter. Since her divorce, R.R. has returned to work as a nurse, but she worries constantly that she will not be able to earn enough money to support herself and her daughter. She has hypertension, asthma, and seasonal allergies for which she is prescribed hydrochlorothiazide 12.5 mg/day, losartan 50 mg/day, montelukast 10 mg/day, albuterol 1-2 puffs every 4-6 hours as needed (PRN) wheezing and shortness of breath, and pantoprazole 40 mg/day. She also takes over-the-counter (OTC) loratadine 10 mg/day and pseudoephedrine 60 mg every 4 to 6 hours PRN for allergies, naproxen 200 mg every 8 to 12 hours PRN for occasional back pain, and polyethylene glycol 17 g daily PRN for constipation. R.R. drinks three or four cups of coffee each morning and one or two glasses of wine four nights each week to help her calm down when she has had a stressful day. She denies any history of psychiatric illness but states she has always been a "worrier." What factors should be considered in the clinical assessment and differential diagnosis of R.R.'s symptoms of anxiety?

A diagnostic decision tree such as that in Figure 83-1 can be used to assist the clinician in differentiating among various causes of anxiety and different anxiety disorders. According to DSM-5 criteria for primary anxiety disorders, the symptoms should not be secondary to any medical (drug or disease) causes (Table 83-2).

SECONDARY CAUSES OF ANXIETY

A diagnosis of anxiety disorder attributable to a general medical condition is warranted when symptoms are believed to be the direct physiologic consequence of a medical condition.[1] A complete physical and laboratory workup, with a thorough medical and psychiatric history, is needed to exclude reversible causes before a primary anxiety disorder diagnosis is considered. Because new onset of anxiety disorders in elderly persons is rare, this can often be attributed to some medical or substance-related cause. The presence of anxiety may complicate the medical picture and have a negative impact on the course of illness. Also, it should be noted R.R. is 49 years old, and the median age for onset of menopause is 52 years. Although not a medical illness, menopausal symptoms also may include sleep disturbances and mood swings.

Medical illness is associated with higher rates of anxiety compared with the general population.[11] In some cases, the anxiety is physically induced by the medical condition, but reactional anxiety may also occur when faced with a medical illness. Successful management of the medical condition often relieves associated anxiety, but short-term anxiety treatment may be beneficial.

When evaluating for possible causes of anxiety, it is also important to consider all medications a person is taking, including OTC drugs such as cough and cold preparations.[12] A diagnosis of substance-induced anxiety disorder is warranted when anxiety symptoms occur in relation to substance intoxication or withdrawal or when medication use causes the symptoms. Among the medications R.R. is taking, pseudoephedrine might be contributing to her anxiety. Other medications that can cause anxiety are listed in Table 83-2. Psychoactive substance abuse, withdrawal from central nervous system (CNS) depressants (e.g., alcohol, barbiturates, benzodiazepines), excessive caffeine intake, and nicotine withdrawal may go unrecognized as underlying precipitants of anxiety. R.R.’s current pattern of alcohol use, although not excessive, may become problematic if she uses alcohol to self-medicate her anxiety symptoms.

Although anxiety symptoms are the hallmark characteristic of anxiety disorders, it is not unique to this diagnostic category. Virtually any psychiatric illness may present with these symptoms. If anxiety symptoms occur only in relation to another psychiatric disorder, then a separate anxiety disorder diagnosis is precluded. Anxiety in these cases may be alleviated with successful treatment of the primary psychiatric disorder. For example, R.R.'s difficulties with fatigue and sleeping may be target symptoms of either anxiety or depression, or possibly both. However, individuals with other psychiatric disorders can also have a primary anxiety disorder. In fact, comorbidity with anxiety disorders is the rule rather than the exception, particularly for depression.[7,13] Concurrent anxiety and depression are associated with greater disability, poorer treatment outcomes, and higher suicide rates than either depression or anxiety alone.

Anxiety in response to life stressors may be severe and functionally detrimental, but could be considered appropriate for the circumstances. Usually, this type of anxiety is self-limiting and brief, subsiding over days to weeks as the person adapts to the new situation. If the person has no history of an anxiety disorder and the symptoms last only a few months, a diagnosis of adjustment disorder with anxious mood may be appropriate. If the symptoms are severe and continue for a prolonged period, a primary anxiety disorder may be present. The initial onset of a chronic anxiety disorder often occurs during a stressful period. Short-term or intermittent therapy with anxiolytic medication or counseling can be extremely beneficial in helping persons cope during times of acute stress. In contrast, management of primary anxiety disorders usually requires more extended treatment.

In summary, the factors in R.R.'s case warranting further investigation before a primary anxiety disorder diagnosis can be made include her medical illness (asthma), possible onset of menopause, her use of pseudoephedrine and caffeine, and her adjustment to the recent life changes (divorce, returning to work, becoming a single mother). These factors need to be addressed and treated, if possible, before a diagnosis of an anxiety disorder can be applied and appropriately managed.

GENERALIZED ANXIETY DISORDER

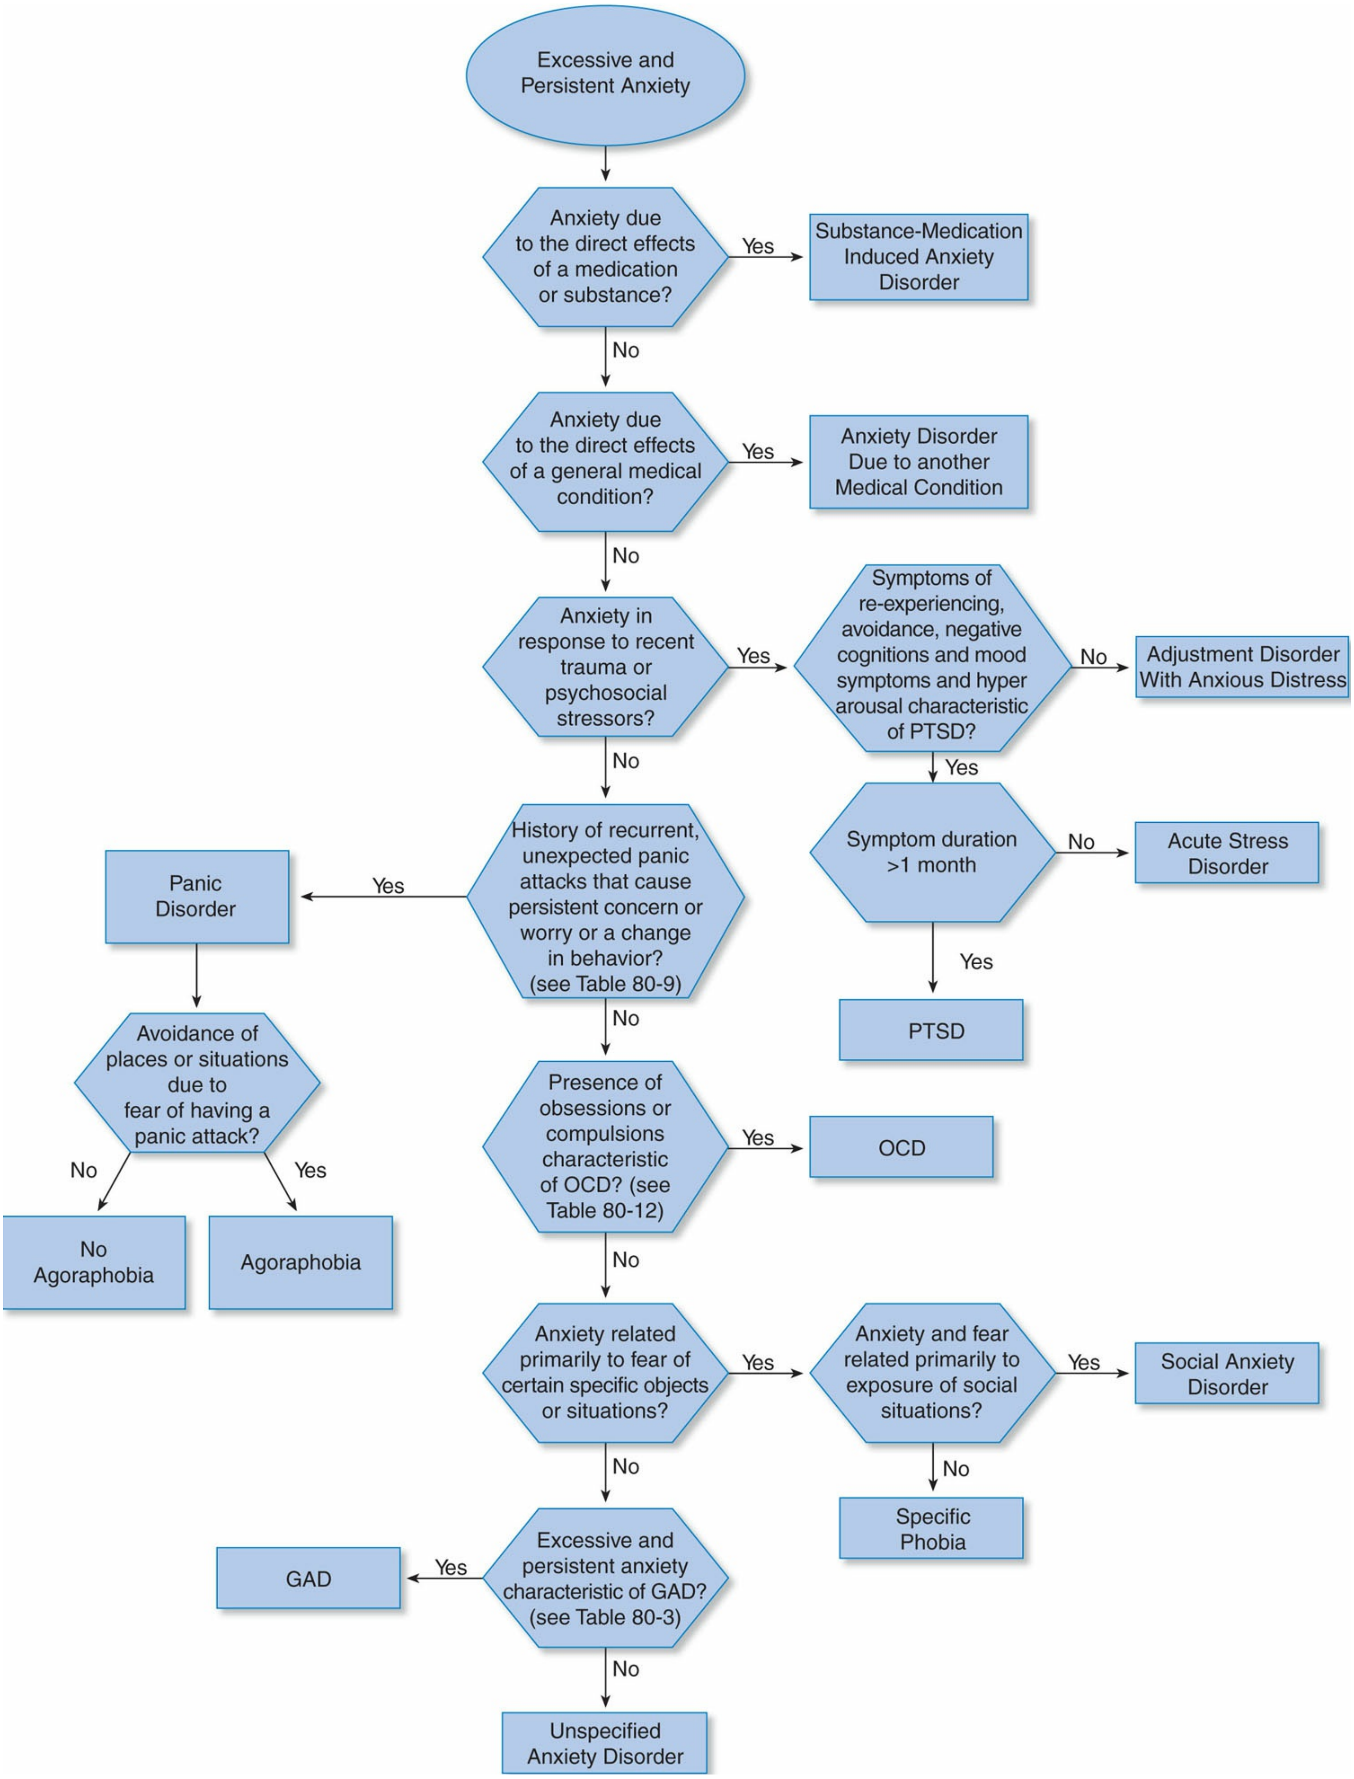
Epidemiology and Clinical Course

Generalized anxiety disorder is one of the most common anxiety disorders, with a lifetime prevalence of about 9% and is twice as common in women than in men.[1,14] Onset is usually gradual and may be associated with increased life stressors. GAD usually begins between the mid-teens and mid-50s and the median age of onset is 30 years.[9,14] As such, GAD presents the latest of all anxiety disorders.[1] Whites are more likely to report anxiety symptoms than Asians, Hispanics, and African Americans.[15] The typical course of GAD is described as being chronic and recurrent, but much is unknown about the long-term course of illness. Without treatment, it appears that less than half of GAD cases undergo remission.

Most people with GAD have at least one other psychiatric disorder. Common comorbid disorders include panic or social anxiety disorder, simple phobia, OCD, and major depressive disorder.[8] Lastly, evidence suggests that GAD itself may be a risk factor for suicidal ideation, particularly among women, even when comorbid substance abuse and depression are considered.[16]

Diagnostic Criteria

GAD is characterized by excessive anxiety and worry about life issues for 6 months or longer.[1] The patient usually has great difficulty controlling the worry, which is accompanied by at least three of the associated symptoms listed in Table 83-3. Although some physical symptoms are similar between GAD and other anxiety disorders, if the anxiety is related solely to another anxiety disorder (e.g., obsession with germs, fear of social situations), a diagnosis of GAD is not warranted.



Excessive and Persistent Anxiety
Anxiety due to the direct effects of a medication or substance?
Yes
Substance-Medication Induced Anxiety Disorder
No
Anxiety due to the direct effects of a general medical condition?
Yes
Anxiety Disorder Due to another Medical Condition
No
Anxiety in response to recent trauma or psychosocial stressors?
Yes
Symptoms of re-experiencing, avoidance, negative cognitions and mood symptoms and hyper arousal characteristic of PTSD?
No
Adjustment Disorder With Anxious Distress
Yes
Symptom duration >1 month
No
Acute Stress Disorder
Yes
PTSD
No
History of recurrent, unexpected panic attacks that cause persistent concern or worry or a change in behavior? (see Table 80-9)
Yes
Panic Disorder
Avoidance of places or situations due to fear of having a panic attack?
No
No Agoraphobia
Yes
Agoraphobia
No
Presence of obsessions or compulsions characteristic of OCD? (see Table 80-12)
Yes
OCD
No
Anxiety related primarily to fear of certain specific objects or situations?
Yes
Anxiety and fear related primarily to exposure of social situations?
Yes
Social Anxiety Disorder
No
Specific Phobia
No
Excessive and persistent anxiety characteristic of GAD? (see Table 80-3)
Yes
GAD
No
Unspecified Anxiety Disorder

Figure 83-1 Diagnostic decision tree for anxiety disorders. GAD, generalized anxiety disorder; OCD, obsessive–compulsive disorder; PTSD, post-traumatic stress disorder.

Table 83-2

Secondary Causes of Anxiety

Medical Illnesses
Endocrine and metabolic disorders: hyperthyroidism, hypoglycemia, Addison disease, Cushing disease, pheochromocytoma, PMS, electrolyte abnormalities, acute intermittent porphyria, anemia
Neurologic: seizure disorders, multiple sclerosis, chronic pain syndromes, traumatic brain injury, CNS neoplasm, migraines, myasthenia gravis, Parkinson disease, vertigo, essential tremor
Cardiovascular: mitral valve prolapse, CHF, arrhythmias, post-MI, hyperdynamic β-adrenergic state, hypertension, angina pectoris, postcerebral infarction
GI: PUD, Crohn disease, ulcerative colitis, irritable bowel syndrome
Respiratory: COPD, asthma, pneumonia, pulmonary edema, respirator dependence, pulmonary embolus
Others: HIV infection, systemic lupus erythematosus
Psychiatric
Depression, mania, schizophrenia, adjustment disorder, personality disorders, delirium, dementia, eating disorders
Drugs
CNS stimulants: amphetamines, methylphenidate, caffeine, cocaine, diethylpropion, ephedrine, MDMA (Ecstasy), nicotine (and withdrawal), PCP, phenylephrine, pseudoephedrine
CNS depressant withdrawal: barbiturates, benzodiazepines, ethanol, opiates
Psychotropics: antipsychotics (akathisia), bupropion, buspirone, SNRIs, SSRIs, TCAs
Cardiovascular: captopril, enalapril, digoxin, disopyramide, hydralazine, procainamide, propafenone, reserpine
Others: albuterol, aminophylline, baclofen, bromocriptine, cycloserine, dapsone, dronabinol, efavirenz, fluoroquinolones, interferon-α, isoniazid, isoproterenol, levodopa, lidocaine, mefloquine, metoclopramide, monosodium glutamate, nicotinic acid, NSAIDs, pergolide, quinacrine, sibutramine, statins, steroids, theophylline, thyroid hormone, triptans, vinblastine, yohimbine

CHF, congestive heart failure; CNS, central nervous system; COPD, chronic obstructive pulmonary disease; GI, gastrointestinal; HIV, human immunodeficiency virus; MDMA, 3,4-methylenedioxymethamphetamine; MI, myocardial infarction; NSAIDs, nonsteroidal anti-inflammatory drugs; PCP, phencyclidine; PMS, premenstrual syndrome; PUD, peptic ulcer disease; SNRIs, serotonin and norepinephrine reuptake inhibitors; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

Table 83-3

Symptoms of Generalized Anxiety Disorder[1]

Anxiety and worry are associated with at least three of the following symptoms (or one in children):

- Restlessness or feeling keyed up or on edge
- Easy fatigue
- Difficulty concentrating or mind going blank
- Irritability
- Muscle tension
- Sleep disturbances

Etiology and Pathophysiology

Genetic factors play a significant role in the etiology of GAD. Genes involved in the hereditary development of GAD are believed to be the same as those for neuroticism and major depression, with environmental factors determining which disorder is expressed in an individual.[5,17,18] Biologic studies in GAD have found abnormalities in noradrenergic, serotonergic, and CCK and GABA-A receptor function.[5] Several studies report decreased α_2-adrenergic receptors in GAD patients, and this is believed to represent downregulation of receptors in response to high catecholamine levels.

Treatment of Generalized Anxiety Disorder

NONPHARMACOLOGIC TREATMENTS

Management of GAD can involve both nonpharmacologic and pharmacologic therapies. Nondrug treatments such as supportive psychotherapy, dynamic psychotherapy, cognitive behavioral therapy (including internet or computer based programs), relaxation training, and meditation are often helpful in relieving anxiety and improving coping skills.[19–21] Cognitive therapy is aimed at identifying negative thought patterns provoking or worsening anxiety and making them more positive. Cognitive behavioral therapy (CBT) has been associated with significant reductions in anxiety that are maintained for 6 to 12 months, as well as decreased psychiatric comorbidity in GAD.[19]

BENZODIAZEPINES

Benzodiazepines are widely prescribed anxiolytic agents, and their efficacy in treating GAD and other anxiety disorders, particularly in the short term, is well established.[22] Benzodiazepines offer rapid symptom relief, but are still associated with risks of dependence and withdrawal and are not recommended for the long-term management of GAD.

Mechanism of Action

Benzodiazepines have four distinct effects: anxiolytic, anticonvulsant, muscle relaxant, and sedative-hypnotic. Benzodiazepines potentiate GABA by binding to sites on the central GABA-A receptor which serve as the main inhibitory neurotransmitter in the CNS.[23] These agents are used to treat a wide variety of medical and psychiatric conditions, including muscle spasms, seizures, anxiety disorders, acute agitation, and insomnia. Benzodiazepines with a rapid onset and short duration of action are commonly used to decrease anxiety and apprehension, as well as induce sedation before surgery and other medical procedures.

Table 83-4

Clinical Comparison of Benzodiazepine Agents

Drug (Trade Name, Generic)	FDA-Approved Indications	Usual Dosage Range Through 65 Years of Age	Maximal Recommended Dosage Through 65 Years of Age	Approximate Dosage Equivalencies
Alprazolam (Xanax, Xanax XR, Niravam orally disintegrating tablets, Intensol oral solution, generic)	Anxiety, anxiety associated with depression, panic disorder	0.5–6 mg/day (up to 10 mg/day for panic disorder)	2 mg/day	1
Chlordiazepoxide (Librium, Limbitrol,[a] Librax,[b] generic)	Anxiety, preoperative anxiety, acute alcohol withdrawal	15–100 mg/day	40 mg/day	50
Clonazepam (Klonopin, orally disintegrating tablets, generic)	Anticonvulsant, panic disorder	0.5–12 mg/day	3 mg/day	0.5
Clorazepate (Tranxene, Tranxene-SD, generic)	Anxiety, alcohol withdrawal, anticonvulsant	15–60 mg/day	30 mg/day	15
Diazepam (Valium, Intensol oral solution, Injection solution, generic)	Anxiety, muscle relaxant, acute alcohol withdrawal, preoperative anxiety, anticonvulsant	4–40 mg/day	20 mg/day	10
Estazolam (ProSom, generic)	Sedative-hypnotic	1–2 mg HS	1 mg HS	2
Flurazepam (Dalmane, generic)	Sedative-hypnotic	15–30 mg HS	15 mg HS	30
Lorazepam (Ativan, oral solution, injection solution, generic)	Anxiety, anxiety associated with depression, anticonvulsant, premedication for anesthetic procedure	2–6 mg/day	3 mg/day	1.5–2
Oxazepam (Serax, generic)	Anxiety, alcohol withdrawal	30–120 mg/day	60 mg/day	30
Quazepam (Doral)	Sedative-hypnotic	7.5–15 mg HS	7.5 mg HS	15
Temazepam (Restoril, generic)	Sedative-hypnotic	15–30 mg HS	15 mg HS	30
Triazolam (Halcion, generic)	Sedative-hypnotic	0.125–0.25 mg HS	0.125 mg HS	0.25

[a] Combination product containing amitriptyline.

[b] Combination product containing clidinium bromide (classified as a gastrointestinal antispasmodic agent).

FDA, US Food and Drug Administration; HS, at bedtime.

Clinical Comparison of Benzodiazepines

Of the 14 benzodiazepines commercially available in the United States, 7 are marketed as antianxiety agents, 6 as oral sedative-hypnotics., and 1 as an anticonvulsant. Indications reflect manufacturers' labeling decisions because anxiolytics can be effective sedatives and vice versa.

Table 83-4 compares the clinical profiles of marketed oral benzodiazepines. Midazolam and clobazam are not included in Table 83-4 as these agents are not used in the treatment of anxiety. Most benzodiazepines have unlabeled uses, including treatment of anxiety and agitation associated with medical or psychiatric illnesses; alcohol withdrawal; irritable bowel syndrome; premenstrual syndrome; chemotherapy-induced nausea and vomiting; catatonia; tetanus; involuntary movement disorders (restless legs syndrome, akathisia, tardive dyskinesia, essential tremor); and spasticity associated with various neurologic disorders (cerebral palsy, paraplegia).

ANTIDEPRESSANT AGENTS

Antidepressants are the recommended first-line treatment for most patients with GAD, though benzodiazepines are widely prescribed. One important distinction between these two medication classes is that the anxiolytic effects of benzodiazepines occur almost immediately, whereas the effects of antidepressants occur gradually over several weeks. Therefore, it is common for short-term benzodiazepine therapy to be prescribed in combination with an antidepressant during initial treatment of many anxiety disorders.[24]

As shown in Table 83-5, selective serotonin reuptake inhibitors (SSRIs) have since gained first-line status for treating all five primary anxiety disorders.[25] Use of these agents, in addition to serotonin and norepinephrine reuptake inhibitors (SNRIs), first line is increasingly common when compared to alternatives due to their tolerability profile as well as utility in treating the common comorbid presentation of depression.

Early controlled studies found trazodone, doxepin, imipramine, and amitriptyline comparably effective or superior to benzodiazepines in treating GAD.[22] Although benzodiazepines work quickly, and TCA treatment is often associated with initial increases in anxiety (especially with higher dosages), continued TCA therapy is usually effective if side effects are tolerated. However, TCAs are not widely used for treating anxiety disorders because attention has turned to other much safer and better tolerated antidepressants, including SSRIs and SNRIs.

Table 83-5

Summary of Comparative Medication Treatment Options for Anxiety Disorders

Disorder	FDA-Approved First-Line Treatments (Unless Otherwise Noted)	Second-Line Treatments	Possible Alternatives
Generalized anxiety disorder	Buspirone Benzodiazepines (short-term use only) Escitalopram Duloxetine Paroxetine Venlafaxine XR	Citalopram Pregabalin Sertraline	Atypical antipsychotics[c] Fluoxetine Mirtazapine Tricyclic antidepressants[b]
Panic disorder	Citalopram[a] Escitalopram[a] Fluoxetine Fluvoxamine[a] Paroxetine Sertraline Venlafaxine	Benzodiazepines (e.g., alprazolam, clonazepam, diazepam, lorazepam) Clomipramine Imipramine Mirtazapine	Anticonvulsants Atypical antipsychotics Phenelzine
Social anxiety disorder	Escitalopram[a] Fluvoxamine CR Paroxetine Venlafaxine XR Sertraline	Benzodiazepines (e.g., alprazolam, clonazepam) Citalopram Pregabalin	Atypical antipsychotics Duloxetine Fluoxetine Gabapentin Mirtazapine Phenelzine[b] Tranylcypromine[b]
Post-traumatic stress disorder	Paroxetine Venlafaxine XR[a] Sertraline	Citalopram Escitalopram Fluoxetine Fluvoxamine Mirtazapine	Amitriptyline[b] Anticonvulsants Atypical antipsychotics[c] Bupropion Duloxetine Imipramine[b] Nefazodone[b] Phenelzine[b] Prazosin
Obsessive–compulsive disorder	Escitalopram[a] Fluoxetine Fluvoxamine Fluvoxamine CR Paroxetine Sertraline	Citalopram Clomipramine[b] Venlafaxine	Anticonvulsants[c] Antipsychotic agents[c] Phenelzine

[a] Not US Food and Drug Administration (FDA) approved for the indication but evidence supports use

[b] Documented efficacy, but not recommended for first-line treatment because of undesirable clinical properties (side effects, potential toxicity, drug interactions).

[c] Adjunctive therapy only.

Paroxetine and escitalopram are SSRIs approved for GAD by the US Food and Drug Administration (FDA). Sertraline and citalopram have also been studied for this indication and the former is the preferred first-line agent according to one guideline.[24] Overall, SSRIs and SNRIs are recommended for first-line use and specific agents should be selected based on patient-specific factors (e.g., risk for discontinuation syndrome, drug interactions, tolerability, and patient preference).[20,25]

Like TCAs, patients may experience an initial increase in anxiety during SSRI treatment, so lower-than-normal SSRI starting doses should be used in patients with GAD, particularly if fluoxetine is utilized, as it may be more likely than other SSRIs to cause anxiety as an initial side effect.[26]

SNRIs, venlafaxine and duloxetine, are FDA-approved for the treatment of GAD. Newer SNRIs including levomilnacipran, milnacipran, and venlafaxine's active metabolite, desvenlafaxine, have not been well studied in the management of anxiety. However, data suggest these agents may be useful for the treatment of anxiety symptoms associated with depression, although further randomized controlled trials are needed to confirm this finding.[27–29] The side effect profile of venlafaxine and other SNRIs is similar to that of the SSRIs, with dose-related nausea being the most common, and this usually subsides after 1 to 2 weeks of continued therapy. Similar to SSRIs, vigilance for worsening anxiety is required upon initiation of treatment and low doses should be utilized to mitigate this potential effect. Significant increases in blood pressure with venlafaxine are not usually seen within the

---

dosage range used for GAD (75–225 mg/day), but can occur with higher doses. Long-term studies report remission of GAD during 6 months of continued treatment with venlafaxine XR.[30] Duloxetine's effectiveness has been demonstrated in short- and long-term trials, with the latter citing a decrease in relapse of GAD in patients treated with 60 to 120 mg/day.[31–35] In a noninferiority comparison of duloxetine 60 to 120 mg/day and venlafaxine XR 75 to 225 mg/day, these agents achieved criteria for noninferiority and demonstrated comparable tolerability.[36]

Mirtazapine is a non-SSRI antidepressant with limited controlled data in the treatment of GAD, though there is limited support in patients with comorbid major depression.[37,38] It is unlikely to cause anxiety as a side effect, owing to its 5-HT receptor type-2 blocking activity. (See Chapter 86, Depression for more information regarding the clinical use of various antidepressant agents.) Finally, vortioxetine has been studied in short- and long-term treatment of GAD with mixed results.[39–42] As mentioned previously, lower initial doses of antidepressants are recommended to avoid acute worsening of anxiety symptoms. Slow titration and patient education regarding adverse reactions associated with antidepressants, including the black-box warning for suicidality, are also recommended.[43] Although decreases in anxiety symptoms during antidepressant treatment may appear within the first 2 weeks, response is gradual and generally continues for 8 to 12 weeks or longer. Therefore, optimal trials of antidepressants in GAD should allow at least 8 weeks of adequate doses before a lack of response is determined. Continued improvements may occur for 4 to 6 months in some GAD patients treated with antidepressants.[44,45]

Overall, advantages of antidepressants compared with benzodiazepines in treating GAD include their superior efficacy for both cognitive symptoms, such as excessive worry, as well as for common comorbid disorders such as depression and other anxiety disorders. Antidepressants also lack potential for abuse and dependence, a safer withdrawal syndrome and no long-term cognitive impairments.

OTHER AGENTS USED TO TREAT GENERALIZED ANXIETY DISORDER

Buspirone was marketed in the United States as the first of a nonbenzodiazepine class of anxiolytics, the azapirones, and is FDA-approved for the treatment of GAD. Buspirone does not interact with GABA receptors and works as a partial agonist of the 5-HT type 1A receptor, reducing 5-HT neurotransmission.[46] In addition, buspirone enhances dopaminergic neurotransmission by blocking presynaptic dopamine receptor-2 autoreceptors and also facilitates noradrenergic activity.[47] Buspirone is effective in treating cognitive anxiety symptoms and is not associated with abuse or dependence; however, it has a delayed onset of anxiolytic effects and is not appropriate for as-needed use.

Pregabalin, a schedule V controlled substance, may be recommended as a second-line agent following use of SSRIs or SNRIs.[20,24] Pregabalin appears to be efficacious in managing somatic and psychic symptoms of GAD compared with active comparators, including benzodiazepines and venlafaxine.[43,48] Further, it has been studied as an adjunctive agent in combination with SSRIs or SNRIs.[49] Although there is a paucity of comparison studies with SSRIs or SNRIs, some guidelines support use of pregabalin as a first-line agent for GAD.[20,50] However, considerations need to made for the potential for weight gain associated with long-term use, as well as limitations with use in individuals with renal disease or those with a history of substance abuse.[25] Pregabalin exhibits a dose–response effect that appears to plateau at 300 mg/day, although one long-term continuation study of up to 24 weeks suggests pregabalin 450 mg/day may be effective in preventing relapse compared with placebo.[51] Further, an open-label study of doses up to 600 mg/day maintained response for up to 1 year.[52]

Finally, atypical antipsychotics are utilized off-label in patients with GAD, though current guidelines highlight that use of these agents should not be initiated in primary care and reserved after multiple antidepressant class failures.[24] Aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone have been studied for treatment-resistant GAD, with the bulk of evidence and current guidelines supporting use of quetiapine.[20,25,53] These agents may be useful in patients who fail to respond to first-line treatment options.[20,24,25]

Clinical Presentation and Assessment of Generalized Anxiety Disorder

CASE 83-2

QUESTION 1: L.V., a 32-year-old man, has been employed as a teacher for the past 10 years. He has had an excellent work record until 8 months ago, when excessive absences and a tendency to become easily upset at students and coworkers became noticeable. On clinical assessment, L.V. complains of being "on edge," irritable, and tense, with frequent stomach upset and diarrhea. He has no history of mental illness; however, he admits to being stressed and worrying too much about "insignificant things." He cannot seem to control these symptoms regardless of how hard he tries. L.V. denies any symptoms indicative of panic disorder or OCD.

L.V.'s physical examination is unremarkable, and his family history is only notable for his sister who is described as a "nervous person." L.V. denies past or present use of any illicit substances and drinks three to four beers at social events, which he has not enjoyed recently. His mental status examination reveals the following:

- Appearance and behavior: L.V. is neatly groomed and dressed and speaks coherently, but he constantly fidgets and taps his right foot.
- Mood: L.V. is anxious and worried about the clinician's evaluation and admits to occasionally feeling depressed and hopeless because of his anxiety. He often has difficulty falling asleep but generally remains asleep throughout the night.
- Sensorium: L.V. is oriented to person, place, and time.
- Thoughts: L.V. denies any auditory or visual hallucinations, or suicidal or homicidal ideation.

L.V. states, at times, that he is unable to relax, particularly in the classroom around his students. His work has been difficult for him lately, and the principal has told him that his job is in immediate jeopardy unless he improves his performance. L.V. states that he just wants to be able to perform his job like he used to and be able to "chill out" and get back to his old life. His insight and judgment are good, and he is motivated to obtain treatment. The physician's provisional diagnosis is GAD.

What clinical features of GAD are present in L.V., and how can his symptoms be assessed objectively?

L.V. exhibits the following target symptoms associated with GAD: excessive worry that is difficult to control, irritability, tension, and inability to relax. Other typical symptoms of anxiety present in L.V. include gastrointestinal (GI) problems (upset stomach and diarrhea), being startled easily, and fidgeting. These target symptoms are not necessarily diagnostic of any particular disorder, but other factors in association with these symptoms are consistent with GAD. The absence of physical or other psychiatric illnesses, as well as use of any illicit substances and lack

---

of recent use of alcohol, excludes possible secondary causes of anxiety. The 8-month duration of symptoms is consistent with a diagnosis of GAD, and L.V.'s age is consistent with the usual onset of GAD. More importantly, the symptoms are causing significant occupational impairment for L.V. and interfering with his quality of life; therefore, a diagnosis of GAD is appropriate in L.V.

The Hamilton Anxiety Rating Scale (HAM-A) is a useful assessment tool to evaluate clinical anxiety, and it is the standard instrument used in GAD clinical trials. A HAM-A score of greater than 18 is generally correlated with significant anxiety, and a reduction of score to 7 to 10 is associated with no symptoms, defined as remission.[54] The HAM-A can be used to assess baseline anxiety symptoms in patients such as L.V. and to monitor response throughout treatment. The Sheehan Disability Scale is a patient-rated instrument, which is commonly used to assess functional impairment caused by GAD and other anxiety disorders. It measures 3 domains from 1 to 10. A score of 1 reflects mild disability whereas a score of 10 suggests severe impairment.[54]

Indications for and Selection of Treatment

CASE 83-2, QUESTION 2: Based on the information presented in L.V.'s case, how can it be determined whether treatment is indicated? What factors should be considered in choosing the most appropriate treatment for L.V.?

L.V. meets the diagnostic criteria for GAD and is suffering significant disability from his anxiety disorder. He also has insight into his illness and desires treatment that will enable him to improve his job performance and quality of life. Appropriate treatment of GAD can help achieve these goals and is therefore indicated for patients such as L.V.

Treatment options for GAD include both pharmacologic and nondrug therapies. Psychosocial treatments such as CBT can be effective in treating GAD, but use of these therapies alone is generally reserved for patients with mild-to-moderate symptoms. In L.V.'s case, prompt treatment is needed because his job is in immediate jeopardy owing to impairments associated with his anxiety. Therefore, pharmacotherapy in combination with psychological therapy, if available, is indicated in L.V.

Among potential drug therapies, short-term use of benzodiazepines, maintenance with SSRIs, SNRIs (duloxetine and venlafaxine), and buspirone are all considered first-line treatments for GAD.[20,24,25] A primary consideration when choosing among these options is whether any comorbid psychiatric conditions are present. Antidepressants are the recommended initial choice for patients with concurrent depression, which is common in GAD patients. Other medical or psychiatric disorders may also be present, which can guide selection toward a treatment that may be dually effective.

Another important consideration when selecting treatment for GAD is how quickly therapeutic effects are needed. Benzodiazepines reduce anxiety within a few hours, whereas antidepressants and buspirone have delayed onsets of anxiolytic effects. Medication cost is another potential factor, and generic benzodiazepines or SSRIs are inexpensive options.

In L.V.'s case, a benzodiazepine may be a good initial choice because of the need for quick symptom relief relating to his problems at work. L.V. is young and healthy with no past or present history of substance abuse or alcohol use that might make benzodiazepines unsuitable for him. Although L.V. drinks beer on occasion at social gatherings, he has not participated in these events recently, and he should continue to avoid alcohol if a benzodiazepine is initiated. GAD is often chronic, and antidepressants or buspirone are recommended over benzodiazepines for long-term treatment. Therefore, one of these agents would also be appropriate to use in this case.

Benzodiazepine Treatment

FACTORS INFLUENCING BENZODIAZEPINE SELECTION

CASE 83-2, QUESTION 3: The physician decides to treat L.V.'s GAD with paroxetine for maintenance and a benzodiazepine for quick control of his anxiety during the first several weeks until the onset of paroxetine's anxiolytic effects. What factors are important in the selection of a particular benzodiazepine agent for L.V.?

Of the available benzodiazepines, none have demonstrated clear superior efficacy in the treatment of GAD. However, certain agents have been used more extensively than others. Alprazolam, lorazepam, clonazepam, and diazepam have been successfully used in the treatment of GAD.

Because of similar overall anxiolytic efficacies of benzodiazepines, other factors must be considered when selecting one agent versus another. Benzodiazepines differ in their pharmacokinetic properties, and these are generally the main factors considered in drug selection (Table 83-6).

Benzodiazepines can be differentiated pharmacokinetically according to their elimination half-lives and their metabolism to active or inactive compounds (Table 83-6). Diazepam (Valium) and chlordiazepoxide (Librium) have half-lives between 10 and 40 hours, and are metabolized by hepatic oxidative pathways to the active metabolite desmethyldiazepam (DMDZ).[23] The metabolite DMDZ has a long half-life, and chronic dosing of benzodiazepines that get converted to DMDZ can result in drug accumulation and prolonged clinical effects.[55] This can be especially detrimental in the elderly, those with liver disease, persons taking other drugs interfering with benzodiazepine metabolism, or those who are poor metabolizers. Although long durations of action make once-daily dosing possible, small, divided daily doses are often used clinically to minimize side effects.

As highlighted in Table 83-6, the elimination half-life of clonazepam ranges from 20 to 50 hours, making once-daily dosing feasible. Alprazolam (Xanax, Niravam) and lorazepam (Ativan) have intermediate half-lives of 10 to 20 hours, and oxazepam (Serax) has a short to intermediate half-life of 5 to 14 hours. Alprazolam, lorazepam, and oxazepam usually need to be taken on a three times a day to four times a day dosing schedule for sustained clinical effects, but an extended-release (XR) preparation of alprazolam allows daily or twice-daily dosing. Alprazolam XR may be associated with fewer CNS side effects than the immediate-release form because peak alprazolam blood levels are lower.[56] Notably, lorazepam, temazepam, and oxazepam are free of active metabolites and are unlikely to accumulate with chronic administration; they are preferred over longer-acting agents in patients with liver disease and in the elderly. Unlike phase 1 oxidative metabolism, phase 2 glucuronidation processes, the pathway for these three agents, do not appear to decline with age.[57]

Benzodiazepines are readily absorbed after oral administration.[23] Lipid solubility varies among the agents, resulting in differences in rates of absorption and speed of onset, as well as duration of clinical effects (Table 83-6). Diazepam and clorazepate have the highest lipid solubilities and the quickest onset of action, which can be desirable when rapid anxiolysis is needed; however, both can produce a “drugged” or “high” feeling in some patients. Highly lipophilic benzodiazepines are also more quickly redistributed out of the brain, which decreases their duration of action acutely.

Diazepam, lorazepam, chlordiazepoxide, and midazolam are also available for parenteral (intravenous [IV] and intramuscular [IM]) administration[23] for treatment of severe agitation or seizures, or for induction of preoperative sedation and anxiolysis. IM injection of both chlordiazepoxide and diazepam can be very painful. Lorazepam is the preferred agent when IM dosing is needed for quick control of anxiety or agitation.

Table 83-6

Pharmacokinetic Comparison of Benzodiazepine Agents

Drug	Elimination Half-Life (hours)[a]	Active Metabolites	Protein Binding (%)	Pathway of Metabolism	Rate of Onset After Oral Administration
Chlordiazepoxide	>100	Desmethyldiazepam	96	Oxidation	Intermediate
Diazepam	>100	Desmethyldiazepam	98	Oxidation (CYP3A4, CYP2C19)	Very fast
Oxazepam	5–14	None	87	Conjugation	Slow
Flurazepam	>100	Desalkylflurazepam, hydroxyethylflurazepam	97	Oxidation	Fast
Clorazepate	>100	Desmethyldiazepam	98	Oxidation	Fast
Lorazepam	10–20	None	85–90	Conjugation	Intermediate
Alprazolam	12–15	Insignificant	80	Oxidation (CYP3A4)	Fast
Temazepam	10–20	Insignificant	98	Conjugation	Intermediate

Triazolam	1.5–5	Insignificant	90	Oxidation (CYP3A4)	Intermediate
Quazepam	47–100	2-Oxoquazepam, N-desalkyl-2-oxoquazepam	>95	Oxidation	Fast
Estazolam	24	Insignificant	93	Oxidation	Intermediate
Clonazepam	20–50	Insignificant	85	Oxidation, reduction (CYP3A4)	Intermediate
Midazolam	1–4	None	97	Oxidation (CYP3A4)	NA

[a] Parent drug + active metabolite.

CYP, cytochrome P-450; NA, not applicable.

Cost is another important factor in benzodiazepine selection. Brand-name benzodiazepines can be relatively expensive, but all are available in less costly generic versions. Potential drug interactions should also be considered in the selection of an agent because they can alter pharmacokinetics and clinical effects (see Case 83-4, Question 1).

Because L.V. is young and healthy and is not taking any other medications, the clinician could choose any benzodiazepine. A shorter-acting high-potency agent, such as lorazepam or alprazolam, would be a reasonable option for L.V. Appropriate starting doses would be lorazepam 0.5 to 1 mg TID or alprazolam 0.25 to 0.5 mg TID. Dosages can be increased every 3 to 4 days, if needed, within the dosage ranges indicated in Table 83-4. L.V. should notice a decrease in his anxiety symptoms within the first few days of treatment. Prescription of a generic formulation is recommended to reduce treatment costs.

ADVERSE EFFECTS AND PATIENT COUNSELING

CASE 83-2, QUESTION 4: Alprazolam 0.25 mg TID is prescribed for L.V. in addition to paroxetine. What side effects may occur with benzodiazepine treatment, and how should L.V. be counseled regarding benzodiazepine therapy?

Overall, benzodiazepines are very safe and well tolerated. Sedation and feelings of tiredness are the most common side effects of benzodiazepines, but sedation can also be beneficial in alleviating insomnia that often accompanies anxiety. Tolerance usually develops to the sedative effects of benzodiazepines within 1 to 2 weeks of continued treatment; consequently, benzodiazepine sedative-hypnotics are recommended for only short-term use.[20,23,25] Tolerance does not appear to develop to the anxiolytic or muscle relaxant effects of benzodiazepines.

Benzodiazepines can cause cognitive impairment and anterograde amnesia (decreased memory for new information after taking the drug), which is dose-related and reversible on medication discontinuation. Tolerance often develops to the cognitive adverse effects, but they can also persist throughout therapy in some patients.[58] Newer studies have demonstrated a possible association with long-term benzodiazepine use and dementia.[59,60] Use of alcohol during benzodiazepine therapy greatly increases the risks for memory problems and sedation, as well as for other more dangerous effects, including respiratory depression. Elderly individuals are more sensitive to sedative, cognitive, and psychomotor effects of benzodiazepines, and tolerance to these effects may occur more slowly than in the nonelderly.[61]

Other psychomotor effects, such as problems with coordination and delayed reaction time, can also occur during benzodiazepine treatment.[23] These effects are also dose-related, but usually subside within a few weeks of continued treatment. Long-acting benzodiazepines taken the previous night may cause residual daytime effects, which can result in car accidents and hospitalization in older individuals receiving these medications.[62]

The link between benzodiazepine use and falls, especially in the elderly, is well documented.[63] Rapid dosage escalation and use of high doses have been identified as major risk factors, but even use of low doses of short-acting agents greatly increases the risk of falling in the elderly.[63–65]

Respiratory depression is another potential adverse effect of benzodiazepines, but it is usually clinically relevant only in patients with severe respiratory disease, in overdose situations (see Case 83-5, Question 1), or when combined with alcohol or substances that depress breathing, like opioids. It is recommended that benzodiazepines be avoided in patients with sleep apnea.

Respiratory complications are encountered most often with IV administration. Severe respiratory depression has also occurred with the concurrent use of benzodiazepines and olanzapine IM (Zyprexa), loxapine (Loxitane), or clozapine (Clozaril). Further, it should be noted benzodiazepines increase the risk of death in prescription drug overdoses, typically in combination with other medications or drugs of abuse.[66]

Paradoxical disinhibition, with increased anxiety, irritability, and agitation, can occur infrequently with benzodiazepines,[23] primarily in elderly or developmentally disabled individuals.[67] Other unusual behaviors, such as increased anger, hostility, depression, suicidal ideation, and rage, have been attributed to benzodiazepine use in a small number of cases.[23,68] Most of these reports were anecdotal and involved patients with preexisting psychiatric disorders such as bipolar disorder or schizophrenia. Overall, there is no convincing evidence that benzodiazepines actually cause violent or suicidal behaviors, but there is some evidence to the contrary.[23,67]

In summary, L.V. should be told he may experience sedation and difficulties in thinking, concentration, or memory during the first week or so of therapy, but these side effects should resolve once he experiences some tolerance to the drug. He should be extremely careful while driving or performing other tasks requiring psychomotor skills, especially during the first week, and he should avoid the use of alcohol while he is taking benzodiazepines.

BENZODIAZEPINE ABUSE AND DEPENDENCE

CASE 83-2, QUESTION 5: Two weeks later, L.V. contacts his clinician to discuss a medication concern. He reports the medication has been extremely effective in relieving his anxiety, and he is currently taking paroxetine 20 mg every morning and alprazolam, 0.25 mg TID, as directed by his physician. However, his friend has told him he will become addicted to alprazolam, and he wonders whether he should stop taking it because of this concern. What potential for abuse and dependence is associated with benzodiazepines? How should L.V. be counseled regarding "becoming addicted" to alprazolam?

Concerns related to abuse and dependence are one major drawback to the clinical use of benzodiazepines. These agents are classified as schedule IV controlled substances. Diazepam, alprazolam, and lorazepam are more likely to be abused than are oxazepam and chlordiazepoxide.[69] This difference is commonly attributed to the quicker onset of effect and high potency which may be associated with a subjective euphoric sensation. The XR alprazolam formulation is reported to have a lower abuse potential than immediate-release alprazolam because of its slower onset of effect smaller peak to trough ratio and lower maximal plasma concentrations.[56]

Patients without a history of substance abuse who take benzodiazepines for therapeutic purposes are unlikely to escalate doses or use them in ways characteristic of abuse.[69]

The potential problems with benzodiazepine abuse and dependence can be avoided or minimized in several ways. First is the identification of patients who have a history of alcohol or substance abuse and using nonbenzodiazepine treatments in such cases.[69] Second, patients should be counseled about the anticipated duration of benzodiazepine use, the possibility of withdrawal symptoms, and the importance of gradual drug tapering when therapy is discontinued. The distinction between "addiction" and appropriate therapeutic use, which may be accompanied by some degree of physical dependence, should be explained.

L.V. should be advised that as long as the medication is helping his anxiety and he is taking it according to his physician's instructions, his use of alprazolam does not constitute addiction. However, his body may develop some physiologic dependence to the drug, so if he stops taking alprazolam abruptly, he could experience increased anxiety and other withdrawal symptoms. When alprazolam is to be discontinued, the dose should be decreased gradually for a sufficient period to minimize withdrawal symptoms.

DURATION OF TREATMENT

CASE 83-2, QUESTION 6: Two weeks later at his clinic appointment, L.V. is still doing well and has shown further improvements in his GAD symptoms. He has been taking the prescribed alprazolam and paroxetine for 1 month, and his paroxetine has been increased to 40 mg/day during this time. How long should medication therapy continue?

GAD is a chronic disorder fluctuating in severity and often requires long-term treatment. Although long-term use of benzodiazepines can be safe and effective, it is desirable to limit treatment to the shortest duration necessary.[20,22,25] When benzodiazepines are used for acute anxiolytic effects during initiation of antidepressant treatment for GAD, they are commonly limited to short-term (2–6 weeks) therapy. L.V. has demonstrated good response after 1 month of combined alprazolam and paroxetine therapy. Because the anxiolytic effects of paroxetine usually occur between 2 and 4 weeks of therapy and he is taking a therapeutic paroxetine dose, it is appropriate to start discontinuing alprazolam at this time. While it is unlikely, L.V. may experience significant withdrawal symptoms even after only 1 month of treatment; thus, the dose should be gradually decreased for several weeks, according to tolerability of the taper.[70] In patients who are treated with short-acting benzodiazepines for longer durations, switching to an equivalent dose of a longer-acting benzodiazepine, like diazepam, may simplify the withdrawal schedule.[71]

There is no consensus about the optimal duration of drug therapy for GAD. However, recent recommendations suggest effective medication treatment be continued for at least 6 to 12 months after response.[22,72] Continuation treatment with antidepressants significantly reduces the risk of GAD relapse in 6 months.[73] Therefore, paroxetine therapy should be continued for another 5 to 11 months in L.V.'s case. After that time, gradual paroxetine discontinuation may be considered, and reinstitution of treatment is warranted if relapse occurs.

SYMPTOMS AND MANAGEMENT OF BENZODIAZEPINE WITHDRAWAL

CASE 83-3

QUESTION 1: T.B., a 48-year-old woman, has been taking diazepam 20 mg BID for 7 months for its muscle relaxant effects after sustaining back and other injuries from a collision with her road bike and an automobile. Five days ago, T.B. was unable to refill her prescription for financial reasons. A brief mental status examination reveals mild confusion and irritability. Physically, T.B. is trembling and complains of nausea and insomnia. Her medical history indicates no current medical problems or psychiatric illnesses, and T.B. denies the use of tobacco, alcohol, or other drugs of abuse. How should T.B. be treated?

Because T.B. has not taken her prescribed diazepam for five days, it is likely she is experiencing a withdrawal syndrome from long-term benzodiazepine use. Her mental and physical symptoms are consistent with benzodiazepine withdrawal. The benzodiazepine withdrawal syndrome implies some degree of physical dependence, and its onset, duration, and severity can vary according to dose, duration of treatment, speed of withdrawal, and elimination half-life of the agent used.[69,70] Withdrawal symptoms that follow discontinuation of agents with short half-lives usually appear within 1 to 2 days and may be more intense and short-lived than after discontinuation of long-acting benzodiazepines. Withdrawal symptoms usually appear 4 to 7 days after discontinuation of long-acting agents and may last several weeks. Symptoms of benzodiazepine withdrawal, which are listed in Table 83-7, are generally mild when the drug is tapered gradually during discontinuation.[70] Rarely, serious symptoms such as seizures or psychosis may occur during benzodiazepine withdrawal. Risk factors for seizures include head injury, alcohol dependence, electroencephalogram abnormalities, and use of other drugs that lower the seizure threshold.

Table 83-7

Symptoms of Benzodiazepine Withdrawal

Common	Less Common	Rare
Anxiety	Nausea	Confusion
Insomnia	Depression	Delirium
Irritability	Ataxia	Psychosis
Muscle aches or weakness	Hyperreflexia	Seizures
Tremor	Blurred vision	Catatonia
Loss of appetite	Fatigue	

Diazepam 10 to 20 mg orally should be administered and repeated within 1 to 2 hours if needed. Resumption of her previous diazepam dosage of 40 mg/day should effectively treat her withdrawal symptoms. However, because her acute injury occurred 7 months ago, it may be desirable to begin tapering diazepam.

Various dosage reduction regimens have been proposed for benzodiazepine discontinuation. Even when managing withdrawal from low-dose benzodiazepine use, doses should be reduced slowly for 4 to 16 weeks.[70] The rate of the drug taper should be individualized to the patient, but a general recommendation is a 10% to 25% decrease in the dosage every 1 to 2 weeks. The first half of the benzodiazepine taper (down to 50% of the original dose) is generally easier and can proceed more quickly than the last half of the taper.[70] In T.B.'s case, the discontinuation period may take several months.

In general, the same benzodiazepine the patient has been taking should be used to manage withdrawal. However, because withdrawal symptoms are more severe during discontinuation of short-acting compared with long-acting benzodiazepines, a long-acting agent can be substituted at an equivalent dosage and then tapered.[70,71] In difficult cases, adjunctive medications, such as anticonvulsants, like carbamazepine or phenobarbital, or propranolol, have been used to ease tolerability of the gradual withdrawal, though the latter does not affect the associated anxiety or decrease the seizure risk.[70,74]

BENZODIAZEPINE DRUG INTERACTIONS

CASE 83-4

QUESTION 1: N.P., a 20-year-old female college student, has been taking alprazolam 1 mg TID PRN for treatment of GAD for the past 2 months. She states alprazolam has been very helpful for her GAD, but complains to her physician she is feeling especially stressed. She is having trouble balancing the increased workload of higher-level courses with her social life, which includes a new relationship. She has no medical illnesses, but states she has suffered from several episodes of heartburn recently, which may be stress-related. She is also interested in starting an oral contraceptive. N.P. smokes two packs of cigarettes per day and drinks up to three 12-ounce caffeinated sodas per day. An oral contraceptive (Yaz) is prescribed, and ranitidine is recommended for treatment of heartburn. What potential drug interactions with alprazolam are present in this case?

The most significant pharmacodynamic drug interactions involve other CNS depressants such as alcohol or barbiturates. These combinations can lead to additive CNS and respiratory depressant effects that can be deadly. Important pharmacokinetic drug interactions mainly involve agents that either inhibit or induce benzodiazepine metabolism.[75] One clinically significant drug interaction occurs with the use of azole antifungals in combination with benzodiazepines. Azole antifungals are potent CYP3A4 inhibitors that can cause a 170% increase in the area under the curve of alprazolam.[76] Therefore, the dosage of alprazolam should be reduced by about one-third in patients receiving this combination. Since benzodiazepines have a relatively wide margin of safety, elevated plasma levels or prolonged elimination half-lives are unlikely to cause serious toxicity. However, they can lead to increased sedative and psychomotor effects, which may be clinically significant in certain cases. Conversely, increased benzodiazepine metabolism by hepatic enzyme inducers may result in medication ineffectiveness. Most pharmacokinetic drug interactions with benzodiazepines involve CYP3A4- or CYP2C19-mediated mechanisms. Please refer to a drug interactions database, such as Facts & Comparisons (**http://www.wolterskluwercdi.com/**) for additional information.

In N.P.'s case, the most important drug interaction is between alprazolam and the newly prescribed oral contraceptive, Yaz. Estrogen-containing oral contraceptives can inhibit the CYP3A4 metabolism of benzodiazepines such as alprazolam, potentially resulting in increased side effects.[77,78] Thus, a reduction in the benzodiazepine dosage may be needed when oral contraceptives are added to ongoing benzodiazepine therapy, as in N.P.'s case. The clearance of benzodiazepines that undergo glucuronidation (lorazepam, oxazepam, and temazepam) can be accelerated by oral contraceptives, but this interaction is probably clinically insignificant.[57,77]

Cigarette smoking increases the clearance of some benzodiazepines (clorazepate, lorazepam, oxazepam), but has no effect on others (diazepam, midazolam, chlordiazepoxide).[79] Overall, the effect of smoking is unpredictable and is most likely to be important in patients who either stop or start smoking while taking a benzodiazepine. N.P. should be urged to quit smoking for the sake of her general health and to prevent substantial risks for serious cardiovascular events occurring in smokers taking oral contraceptives. If N.P. does quit, careful monitoring will be needed to determine whether any alprazolam dosage reduction is necessary.

N.P. should also be encouraged to decrease her soda consumption because caffeine can increase anxiety, thus decreasing the effectiveness of alprazolam. Caffeine has been shown to decrease diazepam concentrations by approximately 22%, but studies with other benzodiazepines are lacking.[75]

BENZODIAZEPINE USE IN PREGNANCY AND LACTATION

CASE 83-4, QUESTION 2: At her clinic visit 2 years later, N.P. is doing very well. She has graduated from college, is happily married, and states she and her husband have decided to start a family. N.P. has discontinued her oral contraceptive in hopes of becoming pregnant soon and has successfully quit smoking. N.P. continues to take alprazolam 0.5 mg twice daily (BID) to TID as needed and wonders whether she should also stop taking this drug before she becomes pregnant. What is the teratogenic potential of alprazolam? What alternative treatments are available for the management of N.P.'s anxiety?

Early reports implicated diazepam in causing several birth deformities, including cleft lip or cleft palate and limb and digit malformations, but later studies failed to support this association.[80–84] Most benzodiazepine anxiolytics are classified as pregnancy category D (however, this language will be modified once the FDA labeling changes for pregnancy and lactation go into effect), indicating there is some evidence of fetal risk but the benefits of the medication may outweigh these risks in certain patients.[80,82] Available evidence suggests benzodiazepine use during the first trimester increases the risk for oral clefts by approximately 2.4-fold, but the absolute risk is increased only 0.01%. Benzodiazepines have not exhibited strong teratogenic effects, but it is always advisable to avoid drug use during pregnancy when possible, especially in the first trimester.[82,84] In patients such as N.P., the benzodiazepine should be tapered and discontinued before she becomes pregnant. Nondrug treatments for her GAD such as relaxation therapy, meditation, biofeedback, or cognitive therapy may be helpful. If necessary, single or repeated small doses of benzodiazepines during the second and third trimesters are unlikely to have important adverse effects on the fetus. In these instances, an agent with a short half-life, such as lorazepam, should be considered.[84] Chronic or large doses, especially of long-acting agents, should be avoided because they may accumulate in the fetus. Perinatal sequelae in newborns of mothers who took benzodiazepines during pregnancy include withdrawal symptoms, sedation, muscle weakness, hypotonia, apnea, poor feeding, low birth weight, and increased risk for preterm birth.[81,85]

The clinical situation of unexpected pregnancy in a woman maintained on benzodiazepines can also arise. The general course of action in such cases is often to discontinue all medications immediately. However, it is unwise to abruptly stop benzodiazepine treatment in someone who has been receiving chronic therapy because the resultant withdrawal syndromes can be detrimental to both mother and child. Benzodiazepine dosages should be tapered as quickly as possible to the lowest dosage necessary and discontinued if possible. The postpartum period is a time of heightened risk for recurrence of anxiety disorders, and new mothers should be monitored carefully for signs of relapse.[86] Benzodiazepines are excreted readily in breast milk, and they should be avoided by nursing mothers, when possible, but use is not absolutely contraindicated.[87] If benzodiazepines are used, short-acting agents with no active metabolites are recommended to avoid sedation, poor feeding, withdrawal, and other effects in the infant.[81,88]

BENZODIAZEPINE OVERDOSE AND USE OF FLUMAZENIL

CASE 83-5

QUESTION 1: S.P. is a 17-year-old young man who is brought to the hospital by his mother. S.P. is barely conscious, and his breathing is slow and shallow. His mother states he "took a whole bottle of diazepam" (5 mg, 30 pills) some time during the previous night. S.P.'s medical history is significant for a severe head injury sustained from a car accident 8 months ago. He currently takes carbamazepine (Tegretol) 200 mg TID for seizure prophylaxis. S.P.'s mother believes diazepam is the only drug he ingested because no other medications are missing. Toxicology is positive for benzodiazepines and negative for other substances. What signs and symptoms are consistent with benzodiazepine overdose? Why is it inappropriate to administer the benzodiazepine antagonist, flumazenil, in this case?

Benzodiazepine overdose is characterized by respiratory and CNS depression, both of which are evident in this case (S.P. is almost unconscious, with slow and shallow breathing). Overdose with benzodiazepines as the sole ingested agent is rarely life-threatening, and full recovery is the usual outcome.[89] Flumazenil is a benzodiazepine receptor antagonist effective in reversing sedation associated with benzodiazepine intoxication. Its effects on respiratory depression are inconsistent, but improved breathing may occur secondarily to increased consciousness.[89]

The primary use of flumazenil is in reversing benzodiazepine-induced conscious sedation (primarily with midazolam) in patients who have been sedated for minor surgical or diagnostic procedures. Flumazenil is also approved for treating benzodiazepine overdose, but this use is controversial because of potentially serious complications (e.g., supraventricular arrhythmia and seizure), and questions about its cost-effectiveness.[90,91] Flumazenil administration does not appear to decrease mortality or length of hospital stay in cases of benzodiazepine overdose; therefore, its use for this purpose has become limited.[90]

Flumazenil is contraindicated in overdoses of any agent that decreases the seizure threshold, such as TCAs. Toxicology screening and an electrocardiogram (ECG) should be performed before flumazenil is administered. Because of a risk of seizures, flumazenil should also be avoided in patients with increased intracranial pressure or a known history of seizures or head injury, in those who have been receiving chronic benzodiazepine therapy, and in patients with a history of recent illicit drug abuse (cocaine, heroin). Administration of flumazenil should occur only when acute seizure management measures are available.

Flumazenil reverses benzodiazepine-induced sedation or coma within 1 to 2 minutes after IV administration. The most common side effects include agitation, dizziness, nausea, general discomfort, tearfulness, anxiety, and a sensation of coldness.[89] Rapid or excessive infusion has been associated with tachycardia and hypertension. The elimination half-life of flumazenil is 41 to 79 minutes, and sedation may recur after 1 to 2 hours, especially when large doses of long-acting benzodiazepines are involved. Repeated flumazenil doses or an IV infusion may be indicated in these cases. Full recovery should be verified (3–4 hours of stable alertness) before patients are discharged after flumazenil administration, and they should be advised to avoid driving or performing other potentially hazardous activities for 24 hours. Flumazenil undergoes extensive hepatic metabolism to its glucuronide conjugate and de-ethylated free acid. Dosage reductions are recommended in patients with liver dysfunction.

Flumazenil is not appropriate in S.P.'s case because of his history of head injury and risk of post-traumatic seizures. Instead, management should involve general supportive measures and mechanical ventilation, if indicated. A psychiatric evaluation is also indicated in this case to identify and address the reasons for S.P.'s overdose.

PHYSIOLOGIC VARIABLES INFLUENCING BENZODIAZEPINES

CASE 83-6

QUESTION 1: B.G., a 68-year-old man, is brought to the emergency department (ED) by his wife after being involved as the driver in a minor car accident. He has no physical injuries except for several small abrasions caused by the car airbag deployment. However, B.G. appears drowsy, is mildly confused, and has an unsteady gait. A toxicology screen reveals no alcohol or other substances, except for clonazepam, which his physician prescribed several months ago. B.G.'s wife states he has been taking 0.5 mg BID, and it has been remarkably effective in improving his mood and anxiety. B.G., who is 5 feet 8 inches tall and weighs 250 pounds, is a recovering alcoholic with moderate liver disease caused by years of heavy drinking. He has successfully maintained his sobriety for nearly 2 years. In addition to clonazepam, B.G. also occasionally takes OTC omeprazole and cimetidine for heartburn. It is determined B.G. is experiencing adverse effects of clonazepam, probably caused by drug accumulation. What factors could be influencing disposition of clonazepam in this patient?

Table 83-8

Physiologic Factors Influencing Benzodiazepine Pharmacokinetics

Factor	Physiologic and Pharmacokinetic Effects	Clinical Significance or Comments
Aging	Increased elimination half-life as a result of increased Vd of all benzodiazepines[92]	Lower benzodiazepine dosages, and possibly less frequent dosing intervals, recommended in the

		elderly
	Decreased clearance of benzodiazepines that undergo oxidative hepatic metabolism (Table 83-6)[93]	Benzodiazepines that undergo glucuronidation (lorazepam, oxazepam) preferred in the elderly
	Decreased plasma proteins may lead to increased free fraction of highly protein-bound benzodiazepines (Table 83-6)	Possible increased clinical effects
	Decreased gastric acidity may lead to increased rate of benzodiazepine absorption	Possible faster onset of clinical effects
Sex	Age-related decrease in hepatic oxidative metabolism of benzodiazepines more pronounced in men	Elderly men may require especially low benzodiazepine dosages
	Increased CYP 3A4 and CYP 2C19 activity in premenopausal women may result in higher clearance of drugs that undergo oxidative metabolism[77]	Possible decreased plasma benzodiazepine concentrations and shorter duration of clinical effects of oxidatively metabolized agents in premenopausal women
	Decreased glucuronidation in women may result in slower clearance of benzodiazepines metabolized by conjugation[77]	Women may have longer elimination half-lives of lorazepam and temazepam and may require less-frequent dosing
	Increased Vd in women owing to lower lean body mass and increased adipose tissue[77]	Possible longer elimination half-lives in women, especially the elderly, and greater drug accumulation
	Lower plasma protein binding in women[77]	Clinical significance unknown
Obesity	Increased benzodiazepine elimination half-lives owing to increased Vd	Increased chance of drug accumulation in obese patients; dosage reductions may be indicated
Liver disease	Decreased clearance and increased elimination half-lives of long-acting benzodiazepines and alprazolam in cirrhosis and hepatitis; no changes with oxazepam or triazolam[57]	Avoid long-acting benzodiazepines, or use significantly lower doses to avoid drug accumulation
	Increased elimination half-life of lorazepam in cirrhosis but not acute hepatitis	Decreased lorazepam dose or increased dosing interval recommended in cirrhosis
Kidney disease	Decreased plasma protein binding may lead to increased free fraction of highly protein-bound benzodiazepines (Table 83-6)[94]	Dosage reductions may be necessary
Ethnicity	Decreased oxidative metabolism (via CYP 2C19) of diazepam and alprazolam in Asians[95]	Asians may require lower doses of diazepam, alprazolam, and possibly other benzodiazepines

CYP, cytochrome P-450; Vd, volume of distribution.

Benzodiazepine pharmacokinetics can be affected by various physiologic factors, listed in Table 83-8.[57,77,92–95] Several of these factors are present in this case and may have contributed to the accumulation of clonazepam with resulting adverse consequences.

B.G.’s age may influence clonazepam disposition. Reductions in both CYP3A4 and CYP2C19 activity have been reported to occur with aging. The glucuronidation metabolic pathways are minimally affected with age, so no such effect is seen with lorazepam or oxazepam.[57] Other factors contributing to longer benzodiazepine half-lives in the elderly include decreased hepatic blood flow and increased volumes of distribution of lipid-soluble compounds (owing to decreased muscle mass and increased fat); the latter can increase a drug's half-life in the absence of any clearance changes. As described in Case 83-3, Question 4, older patients are more sensitive to the sedative and psychomotor and especially cognitive impairing effects of benzodiazepines. For these reasons, benzodiazepines should be avoided in the elderly but if necessary, then the recommended benzodiazepine dosages for patients older than 65 years are generally one-third to one-half of those used in healthy adults (Table 83-4).

Sex also may influence benzodiazepine clearance, but studies yield mixed results.[77,96,97] Women have been reported to have higher CYP3A4 and CYP2C19 activities than men, which may partially explain these findings. Increased CYP3A4 activity in

women disappears after menopause, which may necessitate the use of lower benzodiazepine dosages during the postmenopausal period. Women have slower glucuronidation metabolic processes than men, resulting in lower clearance of agents such as temazepam and oxazepam.[57,77]

Obesity and liver impairment are other physiologic factors relevant to B.G.'s case. Obesity increases the volume of distribution of benzodiazepines and the extent of accumulation of long-acting agents. Significant changes in the elimination half-lives of lorazepam and oxazepam are not observed in obese patients. Liver dysfunction can reduce benzodiazepine elimination rates and prolong their half-lives, resulting in recommendations for decreased dosages. The pharmacokinetics of lorazepam, oxazepam, and temazepam are unaffected by liver disease.

Decreased protein binding of benzodiazepines can occur in patients with renal insufficiency, which may lead to increased free fractions of highly protein-bound agents. However, no significant changes in clearance or volume of distribution of free drug have been noted. Regarding ethnicity, up to 25% of Asians are CYP2C19 poor metabolizers. Decreased clearance of a variety of CYP2C19 substrates, including diazepam, has been reported in Asian subjects.[98]

In summary, the physiologic factors that can alter benzodiazepine disposition in B.G. are his age, obesity, male sex, and liver disease. Accumulation of clonazepam owing to these combined effects probably led to his mental status changes. In addition to these factors, cimetidine and omeprazole can both increase the exposure of clonazepam, resulting in decreased clearance and increased side effects.

If continued benzodiazepine therapy is deemed necessary for B.G., lorazepam or oxazepam would be preferred agents because they are least affected by aging, obesity, liver disease, or drug interactions. Benzodiazepine dosage equivalencies, which are based on relative potencies, can be used to determine an equivalent dose for the selected agent (Table 83-4). However, these equivalencies are inexact, and dosing conversions should take patient variables and usual dosage ranges into consideration. For example, B.G. had been taking 1 mg/day of clonazepam, so the calculated equivalent lorazepam dosage is 3 to 4 mg/day. Because of his age and recent reaction at this dose, a somewhat lower initial dose of 0.5 to 1 mg BID would be indicated, accompanied by careful monitoring for adverse effects or withdrawal symptoms. However, switching to a nonbenzodiazepine agent should be considered because this may be a better treatment option for B.G.

Buspirone Therapy

CASE 83-6, QUESTION 2: Several days after recovery from clonazepam intoxication, B.G. expresses a desire to discontinue benzodiazepine use. He is being criticized by his fellow Alcoholics Anonymous program members for taking a drug associated with dependency. The decision is made to switch B.G. from clonazepam to buspirone. How does the clinical profile of buspirone compare with benzodiazepines?

Buspirone lacks CNS depressant effects, sedation, cognitive or psychomotor impairment, respiratory depression, and muscle relaxant or anticonvulsant effects.[46] This makes buspirone useful in older patients who may have a variety of chronic medical conditions. Buspirone is generally well tolerated, and possible side effects include mild nausea, dizziness, headache, and initial nervousness.[99] Unlike many antidepressants, buspirone does not adversely affect sexual functioning and has actually improved sexual functioning in some patients with GAD.[47] Buspirone has minimal potential for abuse and is not classified as a controlled substance. It does not produce physical dependence or withdrawal syndromes on discontinuation, even after long-term therapy.[46,100] It also does not interact with alcohol or other CNS depressants and is relatively safe in overdose.[46]

Buspirone is a 5-HT1a receptor agonist/antagonist and is as effective as benzodiazepines such as alprazolam, oxazepam, lorazepam, diazepam, and clorazepate in the treatment of GAD.[99,100] Like antidepressants, buspirone is more effective than benzodiazepines in treating the cognitive symptoms of anxiety. However, the anxiolytic effects of buspirone have a more gradual onset than benzodiazepines. Initial effects are observed within the first 7 to 10 days, but 3 to 4 weeks may be needed for optimal results. Buspirone must be taken on an ongoing basis if it is effective, and the drug should not be taken “as needed.”

SWITCHING FROM BENZODIAZEPINE TO BUSPIRONE THERAPY

CASE 83-6, QUESTION 3: How should B.G. be switched from benzodiazepine to buspirone therapy?

Because buspirone has no CNS depressant effects and is not cross-tolerant with the benzodiazepines, it is not effective in preventing or treating benzodiazepine withdrawal. Thus, when patients are converted from benzodiazepine to buspirone therapy, the benzodiazepine must be discontinued gradually. Because it takes several weeks for full therapeutic effects of buspirone to occur, it can be initiated before the benzodiazepine taper begins. This may indirectly ease benzodiazepine withdrawal by providing extra anxiolytic coverage during the benzodiazepine taper period.[101]

Administration with food may significantly increase bioavailability by decreasing the first-pass effect. Some of the side effects of buspirone, such as nervousness, are attributed to its active metabolite, 1-pyrimidinylpiperazine (1-PP).[46,102] The mean elimination half-life of buspirone is short, approximately 2 to 3 hours, but 1-PP is longer acting.

The clearance of buspirone is significantly reduced in patients with kidney or liver disease, but there is little change in side effects or tolerability.[46] Nevertheless, it is recommended that buspirone dosages be lowered in patients with compromised renal or hepatic function and that use of the drug be avoided in cases of severe impairment.

Buspirone is metabolized by CYP3A4, and coadministration of CYP3A4 inhibitors, including grapefruit juice, can result in significant increases in buspirone levels.[46] Because of buspirone's extremely wide margin of safety and tolerability, even very large increases in its plasma levels may be clinically insignificant. Buspirone should be avoided in patients taking MAOIs and used cautiously in combination with high-dose antidepressants because of the risk of serotonin syndrome.

Some studies suggest patients previously treated with benzodiazepines will not respond favorably to buspirone.[72,100] However, buspirone may provide benefit in this population as long as the benzodiazepine is tapered slowly enough to prevent withdrawal effects.[22] B.G. has been taking diazepam for several months and the drug needs to be withdrawn gradually during a period of at least several weeks. B.G. can be started on buspirone at this time. The usual recommended starting dosage of buspirone is 15 mg/day given in two to three divided doses, but a lower dosage (10 mg/day) is indicated in B.G. because of his liver disease. Twice-daily dosing is preferred to facilitate compliance and is comparable in efficacy and tolerability to three-times-daily dosing.[103] The daily dosage may be increased in 5-mg/day increments every 3 to 4 days. Optimal anxiolytic doses generally range from 20 to 30 mg/day, with 60 mg/day being the recommended maximum. There are no specific guidelines for adjusting dosages in patients with liver impairment; therefore, dosage titrations in B.G. should be made slowly, according to his response and side effects.

PANIC DISORDER

Diagnostic Criteria

The hallmark characteristic of panic disorder is the occurrence of sudden and distinct panic attacks, which are marked by an overwhelming wave of symptoms and feelings reaching their peak within 10 minutes. Symptoms are listed in Table 83-9. To meet diagnostic criteria, at least one of the attacks must be followed by symptoms lasting at least 1 month, including persistent worry or concern about the consequences of the attack or significant behavior change related to the attack.[1] Experiencing less than the four required symptoms to fulfill diagnostic criteria is termed a "limited symptom attack." Three types of panic attacks have been defined with regard to the context in which they occur: unexpected or uncued panic attacks (the attack is not associated with a situational trigger); situationally bound panic attacks (the attacks invariably occur on exposure to a situational trigger); and situationally predisposed panic attacks (the attacks are more likely to, but do not invariably, occur on exposure to a situational trigger).[1]

Although panic attacks are the hallmark symptom of panic disorder, their occurrence can also be associated with depressive and other anxiety disorders.[1] For example, situationally predisposed panic attacks may occur in either panic or phobic disorders. Nocturnal panic attacks, which awaken a person from sleep, are almost always indicative of panic disorder. Because panic attacks occur unpredictably, they often lead to generalized anxiety or constant fear of sudden attacks.

Epidemiology and Clinical Course

Although the estimated lifetime prevalence of panic disorder is 6.8%, approximately 10% of persons experience recurrent panic attacks that do not fulfill the diagnostic criteria for panic disorder and nearly 30% experience a single isolated panic attack at some point in their lives.[14] The onset of panic disorder often occurs during stressful periods, usually in the late teens to mid-30s, with rare first onset in the elderly population.[8,77] Women are affected two to three times more often than men.[77]

Panic disorder, like other anxiety disorders, is accompanied by marked degrees of psychiatric comorbidity. Common comorbidities include other anxiety disorders, affective disorders, personality disorders, and alcohol/substance use disorders with the majority of patients suffering a major depressive episode at some point.[1,14,104,105] Patients with psychiatric and medical comorbidities have more severe symptoms, respond more slowly to treatment, have a lower chance of reaching remission, and have a greater suicide risk (particularly when depression or substance abuse are present) than those with panic disorder alone.[106] Although most patients experience episodic periods of remission and relapse, nearly one in five suffer almost continuously.[107]

Table 83-9

Symptoms of Panic Disorder[1]

- Palpitations, pounding heart, or increased heart rate
- Sweating
- Trembling or shaking
- Sensations of shortness of breath or smothering
- Feeling of choking
- Chest pain or discomfort
- Nausea or abdominal distress
- Feeling dizzy, unsteady, lightheaded, or faint
- Derealization or depersonalization
- Fear of losing control or going crazy
- Fear of dying
- Paresthesias
- Chills or hot flushes

Panic disorder is associated with very high rates of healthcare service utilization.[106] The vast majority of patients with panic disorder do not complain of feeling anxious and report only physical symptoms, such as chest pain, GI problems, headache, dizziness, and shortness of breath, which contributes to misdiagnosis.[108] The poor recognition of panic disorder in primary-care settings further increases use of medical services. Panic disorder is the underlying cause of symptoms in an estimated 10% to 30% of patients referred to specialty vestibular, respiratory, or neurology clinics, and up to 60% of those referred for cardiology consultation.[1] It is not uncommon for patients to have been in the healthcare system for up to 10 years before they are correctly diagnosed.

Etiology and Pathophysiology

A neurobiologic model for panic disorder has been proposed in which the amygdala is the central hub of the fear circuit.[5,109] Various projections from the amygdala, including the hypothalamus and the locus coeruleus, trigger autonomic and neuroendocrine responses resulting in anxiety and panic attacks. Patients with panic disorder have a heightened anxiety sensitivity (fear of anxiety-related sensations), and a variety of substances and situations may activate the anxiety and panic response.[109] Acute panic attacks are believed to be caused by dysregulated firing in the LC as described previously (see Neurobiology of Anxiety section), and hyperresponsiveness of the NE system may be an underlying cause for panic disorder.[110]

Other neurobiologic research suggests patients with panic disorder have abnormal patterns of cerebral glucose metabolism in certain brain areas; abnormalities in

GABA-A receptor, NE, 5-HT, and CCK functioning; decreased GABA-A benzodiazepine binding sites; abnormal regulation of neuroactive steroids that modulate GABA-A receptors; hyperactivation of the HPA axis; CCK-B receptor gene polymorphism; and are hypersensitive to carbon dioxide. These findings seem to predispose patients to panic attacks and require further study.[105,109–111]

Genetic and environmental influences both contribute to a familial pattern where people are 8 to 21 times more likely to develop panic disorder if they have a first-degree relative with the disorder.[1,17] The vulnerability is believed to involve heightened anxiety sensitivity whereby harmless normal physical sensations are misinterpreted as being dangerous and cause fear.[112] Several studies have shown distressing childhood events (e.g., separation from parents and abuse) and behavioral inhibition during childhood (e.g., excessive fear and avoidance of novel stimuli) are associated with markedly increased risks of developing panic disorder later in life.[109] No single biologic abnormality can explain panic disorder, and further research is needed to define the complex interplay of the various pathophysiological, genetic, and environmental findings in this illness.

Treatment of Panic Disorder

Approximately 70% to 90% of patients with panic disorder can experience substantial relief with currently available treatments, which include both pharmacologic therapies and CBT.[1,105] Medications and CBT both are beneficial for reducing panic attacks initially, and their effects on phobic avoidance generally occur later. First-line medication treatments for panic disorder are SSRIs and venlafaxine as TCAs are less tolerable and possess more safety and drug–drug interaction concerns.[20,25,112,113] Benzodiazepines also are effective but no longer recommended as first-line treatment given their abuse liability, cognitive and psychomotor impairments, and lack of efficacy at treating common comorbidities. The

---

heightened anxiety sensitivity common in panic disorder makes patients especially vulnerable to initial SSRI and TCA side effects, such as anxiety and agitation. For this reason, lower-than-usual starting doses of antidepressants are recommended in patients with panic disorder.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Paroxetine, sertraline, fluoxetine, and venlafaxine are FDA-approved for treating panic disorder although other SSRIs (fluvoxamine, citalopram, escitalopram) are also effective in reducing the frequency of panic attacks, anticipatory anxiety, and associated depression.[20,25,113] Although low starting dosages are recommended (10 mg/day for paroxetine and citalopram, 25 mg/day for sertraline, 5–10 mg/day for fluoxetine and escitalopram) to minimize side effects, higher doses relative to antidepressant doses are usually required for response. The recommended target dosage range is 20 to 40 mg/day for paroxetine, citalopram, and fluoxetine, 100 to 200 mg/day for sertraline and fluvoxamine, and 10 to 20 mg/day for escitalopram for panic disorder.[112] The initial dose of venlafaxine XR should be 37.5 mg/day with a recommended therapeutic dose of 150 to 225 mg/day.[112]

Response to SSRIs and other antidepressants in panic disorder occurs gradually, over the course of several weeks. Reduced frequency of panic attacks usually begins within 1 to 2 weeks. A trial period of at least 6 weeks should be allowed to fully assess response, and continued improvements may be seen during a treatment period of 6 months or longer.[112]

BENZODIAZEPINES

The benzodiazepines alprazolam and clonazepam are FDA-approved for treating panic disorder and are the most extensively studied agents of this class although lorazepam and diazepam, when used in equivalent doses, also appear effective.[108,112]

Optimal benzodiazepine dosing is an important issue in treating patients with panic disorder because these individuals may need higher doses for response than patients with other anxiety disorders.[114] This may be related to reduced sensitivity of benzodiazepine binding sites in panic disorder.[115] An alprazolam dosage range of 4 to 6 mg/day is effective for most panic disorder patients, but others may require up to 10 mg/day for optimal response. The total daily dose usually needs to be taken in three or four divided doses to minimize breakthrough anxiety or panic attacks before the next scheduled dose because of fluctuating serum levels given its relatively short duration of action. The extended-release alprazolam formulation (alprazolam XR) was developed to address this problem.[56] It may have a lower abuse liability than immediate-release alprazolam, but this remains unproven. Patients with panic disorder are especially sensitive to benzodiazepine withdrawal effects. For these reasons, using the longer-acting benzodiazepine clonazepam (1–2 mg/day dosed twice daily) may be preferred over alprazolam.[114]

TRICYCLIC ANTIDEPRESSANTS, MONOAMINE OXIDASE INHIBITORS, AND OTHER ANTIDEPRESSANTS

TCAs were the first medications widely used in the treatment of panic disorder. Imipramine (100–300 mg/day) and clomipramine (50–150 mg/day) are as effective as alprazolam, but are less well tolerated.[116] Evidence for most other TCAs is lacking.[20,25,112,113] Clomipramine appears to be more effective than other TCAs for panic disorder, perhaps because of its greater serotonergic effects.[117] Despite using lower initial doses to minimize anxiety-like side effect, many patients discontinue therapy because of poor tolerability.

Among the MAOIs, phenelzine is often heralded as being remarkably effective in the treatment of panic disorder, but this claim is based on studies conducted before the publication of the initial diagnostic criteria for panic disorder in 1980.[112] No recent MAOI studies are available to assess phenelzine's efficacy within the context of current diagnostic and treatment standards. It is generally an option of last resort for treatment-refractory cases because of the many clinical disadvantages of MAOIs relative to other antidepressants (see Chapter 86, Depression).

Preliminary reports suggest mirtazapine may also be beneficial in treating panic disorder.[20,112] This agent may be useful in patients who do not respond to SSRI therapy.[112]

MISCELLANEOUS AGENTS

Other medications that are reportedly effective in treating panic disorder include anticonvulsants (valproic acid and levetiracetam) and antipsychotics (primarily risperidone and olanzapine) as either monotherapy or adjunctive therapy used in combination with an SSRI.[20,112] More information is needed before any of these can be routinely recommended for treating panic disorder.

NONPHARMACOLOGIC TREATMENTS

CBT, including exposure treatment and relaxation training, is also established as being effective in panic disorder.[105,112] The cognitive theory of panic disorder is based on the observed heightened anxiety sensitivity in these patients and asserts that physical anxiety sensations are misinterpreted as being serious or life-threatening. These fears trigger a cycle of further worsening anxiety symptoms that finally progress to a panic attack. Reversing the cognitive component of this vicious cycle is an integral part of CBT and is important in producing lasting therapeutic effects of treatment.[112] Breathing retraining and exposure to fear cues are key components of behavioral therapy.

Some studies have found medications to be superior to CBT in the treatment of panic disorder, whereas others report opposite results.[112,118] Combining medication with CBT can be useful to increase response/remission rates in those with severe symptoms or a partial response as well as to improve relapse rates during pharmacotherapy discontinuation attempts.[20,114,119]

Clinical Presentation and Differential Diagnosis of Panic Disorder

CASE 83-7

QUESTION 1: S.K., a 24-year-old female graphic artist, presents to the ED complaining of chest pain, difficulty breathing, dizziness, and nausea. She describes feeling “as if my head is going off in space and I am outside my body.” These attacks often escalate quickly peaking within 10 minutes and then start to subside within 30 minutes. She states she has been under extreme stress lately because of the poor economy and has conflicts with her landlord as a result of nonpayment of the rent on her art studio. S.K. fears she has had a heart attack or stroke brought on by her stressful life. S.K. recently visited her family physician for the same symptoms; however, a complete physical examination and laboratory workup yielded no abnormalities. She states her first “attack” occurred out of the blue about 5 months ago while she was shopping for oil paints at the art supply store, and she can never predict when they will occur. Since then, her symptoms have become more severe and frequent, and she has started isolating herself in her studio for fear they will return when she is in public. S.K. uses marijuana “to relax” and occasionally drinks alcohol (but only rarely). She has suffered from depression in the past and was hospitalized for one severe episode 2 years ago. An ECG is performed and found to be normal. The physician’s diagnosis is panic disorder with agoraphobia. What clinical features of panic disorder does S.K. display, and what are the important factors in the differential diagnosis of panic disorder?

S.K. exhibits many typical characteristics of panic disorder. As illustrated in this case, the first panic attack typically occurs without warning while the person is involved in a normal everyday activity and lasts 10 to 30 minutes. Panic attacks are extremely terrifying and usually leave the sufferer feeling anxious and convinced something is medically wrong. As with S.K., it is not uncommon for persons to make ED visits after or during panic attacks, believing they have had a heart attack or other serious event. Unfortunately, panic disorder is often not recognized in primary-care settings, and no medical cause for the symptoms can be identified. Faced with findings that they are apparently healthy, persons may make repeated ED visits and consult different doctors and specialists in an attempt to uncover a physical explanation for their frightening symptoms.

S.K. exhibits the following target symptoms of panic disorder: chest pain, shortness of breath, dizziness, abdominal distress, and loss of control. Agoraphobia is present because she avoids leaving her studio because of her fear of having panic attacks. Other factors consistent with a diagnosis of panic disorder include her young age, female sex, and lack of abnormal physical findings. This case also illustrates the association between onset of panic disorder and stressful life events, its common association with depression, and the frequent lack of recognition of panic disorder in primary-care settings.

Because different substances or medical conditions can cause severe anxiety and panic, it is necessary to rule out these potential causes for panic attacks.[108] Notable triggers of panic attacks include caffeine, alcohol, nicotine, nonprescription cold preparations, cannabis, amphetamines, and cocaine (Table 83-2).[108] S.K. uses marijuana, which can be associated with panic symptoms. Although chronic moderate-to-severe use of marijuana may complicate the treatment of panic disorder, it appears infrequent marijuana use does not adversely affect treatment.[120,121] S.K. does not endorse chronic, severe marijuana abuse, but if she does not adequately respond to treatment, this might be further explored. Medical illnesses that can cause panic attacks include thyroid dysfunction, asthma, COPD, mitral valve prolapse, and seizure disorders.[122] Panic attacks can also occur with other anxiety disorders. However, in these cases, the panic attacks usually occur on exposure to a feared object or situation (in phobic disorders), an object of obsession (in OCD), or a stimulus associated with a traumatic stressor (in PTSD). S.K. reports her panic attacks occur unexpectedly, and situationally bound or predisposed attacks are not evident; therefore, the features are consistent with panic disorder.

Treatment Selection for Panic Disorder, Selective Serotonin Reuptake Inhibitor Dosing Issues, and Combination Selective Serotonin Reuptake Inhibitor–Benzodiazepine Therapy

CASE 83-7, QUESTION 2: S.K. is referred to a psychiatrist who decides to initiate treatment with paroxetine 20 mg every morning. Three days later, S.K. calls the doctor complaining that her anxiety and panic attacks have greatly increased since she started taking paroxetine. The psychiatrist prescribes alprazolam 0.5 mg (tablets) and instructs S.K. to take one tablet as needed for the anxiety. What factors should be considered in the selection of an initial medication treatment for panic disorder? Why is the prescribed treatment for S.K. inappropriate?

An SSRI is an appropriate first-line treatment for most panic disorder patients.[20] In patients such as S.K. who have a history of depression, SSRIs may also help prevent relapse of depression. Patients with severe or distressing symptoms may initially require concurrent benzodiazepine therapy, which provides quick relief from anxiety and panic attacks until the therapeutic effects of SSRIs are evident. At that time, usually after several weeks, the benzodiazepine can be gradually discontinued. An SSRI–benzodiazepine combination is still the most commonly prescribed initial treatment, even though guidelines recommend monotherapy unless initial anxiety is extremely high.[123] Although benzodiazepines are generally avoided in patients with a history of substance abuse, use of low doses for a limited time may be appropriate for some patients with disabling symptoms, as long as there is no current substance (especially alcohol) abuse.[20,69,112] Because of the levels of distress and impairment caused by S.K.'s panic disorder, combined SSRI–benzodiazepine therapy would have been the preferred initial treatment. Because panic attacks peak quickly and generally last less than 30 minutes, an as-needed benzodiazepine is not helpful to prevent panic attacks. As such, scheduled benzodiazepine dosing is preferred over as-needed dosing schedule during initial therapy.[112]

In choosing among SSRIs for the treatment of panic disorder, paroxetine or sertraline may be less anxiety provoking in some patients than a more activating SSRI such as fluoxetine.[26] When paroxetine is used, a very low initial dose of 10 mg/day should be used. In S.K.'s case, the prescribed 20-mg/day starting dose was too high.

Also, scheduled versus as-needed benzodiazepine dosing would have been preferred. After 2 to 4 weeks, the benzodiazepine can be gradually discontinued while the SSRI therapy is continued and gradually titrated to the target effective dose. The potential for drug interactions must also be kept in mind when SSRI–benzodiazepine combinations are used because certain SSRIs can inhibit benzodiazepine metabolism, leading to increased benzodiazepine side effects (see Benzodiazepine Drug Interactions section).

Patient Counseling Information

Patients such as S.K. who are beginning SSRI therapy for the treatment of panic disorder should be counseled about possible increased anxiety during the first 1 or 2 weeks of treatment, as well as other common SSRI side effects, including nausea, headache, sexual dysfunction, and either insomnia or sedation. Because these are dose-related effects, patients should inform their clinician of any problems, and a dosage reduction may be indicated. These adverse effects (with the possible exception of sexual dysfunction) usually subside after 1 to 3 weeks of continued treatment. It is also important to inform patients it may take several weeks before beneficial effects of antidepressant treatment are seen, and 6 to 12 weeks or longer may be required for full response. Patients receiving benzodiazepines should be counseled about their use in providing anxiolytic coverage during the initial weeks of SSRI therapy, as well as their limited utility as long-term therapy. Other pertinent counseling information for benzodiazepine treatment should also be included (see Case 83-2, Question 4). The desired goals of therapy and likely duration of treatment should also be explained. Providing information about the nature of panic disorder, including reassurance that panic attacks are not life-threatening, is also important. Many clinicians recommend patients keep a "panic diary" in which they record frequency of panic attacks, along with symptoms experienced during attacks.

Clinical Assessment and Goals of Therapy

CASE 83-7, QUESTION 3: S.K. refuses to continue paroxetine, so escitalopram is prescribed instead. After 1 week of escitalopram therapy at the initial dosage of 5 mg/day, S.K. is tolerating the medication well. The plan is to gradually increase escitalopram to 10 mg, then to 20 mg/day during the next several weeks. S.K. is also taking alprazolam, 0.5 mg BID to TID. What are the desired goals of treatment in this case, and how can S.K.'s response to treatment be assessed?

Five domains in panic disorder have been identified in which treatment outcomes should be assessed: (a) frequency and severity of panic attacks, (b) anticipatory anxiety, (c) phobic avoidance behaviors, (d) overall well-being, and (e) illness-related disability in various areas (work, school, family).[112] The treatment goals in this case are first to stop S.K.'s panic attacks, then to reduce her anticipatory anxiety, followed by reversal of phobic avoidance.[54] These outcomes should allow her to more comfortably leave her studio when required and, secondarily, improve her overall functioning and quality of life.

Several different instruments have been used to assess outcomes of treatment in panic disorder.[54] In addition to the panic diary, others include the Fear Questionnaire, the Panic Appraisal Inventory, and the Panic Disorder Severity Scale. The latter is currently considered by many experts to be the most useful because it evaluates outcomes in all five identified target domains of panic disorder.[54,112]

Course and Duration of Therapy

CASE 83-7, QUESTION 4: After 3 months of escitalopram therapy, S.K. reports she has had no panic attacks in the past month and her functioning has improved dramatically. She is currently taking 20 mg/day of escitalopram and gradually stopped taking the alprazolam 3 to 4 weeks ago. S.K. reveals she is painting regularly, selling some of her paintings, paying her rent, and she has begun dating again. S.K. is experiencing no significant side effects from escitalopram except for some decrease in her sexual drive. She wonders how long she should continue taking it since she is doing so well. What is the recommended duration of treatment for panic disorder?

Long-term medication trials in panic disorder support the recommendation that treatment should continue for at least 6 to 12 months after acute response.[20,112] The benefits of maintenance pharmacotherapy in preventing relapse are well documented although the optimal duration of treatment is a subject of continued debate among panic researchers. Maintenance treatment gives patients time to resume normal lifestyles and to re-establish daily activities after acute cessation of panic attacks.

In this case, S.K.'s current escitalopram dosage of 20 mg/day is appropriate because this is within the effective dosage range for panic disorder. Escitalopram therapy should be continued at the current dosage for 3 to 6 more months. S.K.'s sexual dysfunction is not likely to decrease with continued treatment; therefore, specific remedies for SSRI-induced sexual dysfunction may be tried (see Chapter 86, Depression). After a successful period of full remission, a trial of medication discontinuation may be attempted to determine whether continued treatment is necessary. Medication should not be stopped in patients who are experiencing stressful life events or substantial residual problems in any of the five domains (frequency and severity of panic attacks, anticipatory anxiety, phobic avoidance behaviors, overall well-being, and illness-related disability in work, school, and family).[112] When a medication is discontinued, it should be withdrawn gradually over several months, regardless of the class. Because of the devastating impact panic disorder can have, reinstitution of drug treatment is indicated if relapse occurs. Long-term treatment with antidepressants, and benzodiazepines if necessary, is generally successful in maintaining treatment benefits without detrimental effects or dosage escalations.

SOCIAL ANXIETY DISORDER AND SPECIFIC PHOBIAS

Classification and Diagnosis of Phobic Disorders

The DSM-5 includes two primary types of phobic disorders: specific phobia and social anxiety disorder (formerly social phobia) with symptoms presented in Table 83-10.[1] These disorders involve excessive or unreasonable fears and lead to avoidance behavior to minimize anxiety for a duration of at least 6 months. The main difference between specific phobias and social anxiety disorder is that the former involves fear and avoidance of specific stimuli and not a general fear of social situations.

SOCIAL ANXIETY DISORDER

Social anxiety disorder manifests as intense irrational fear, anxiety, or avoidance of scrutiny or evaluation by others in social situations because of concerns about humiliation or being made to appear ridiculous.[1] A defining feature is that the fears and anxiety are confined to social situations (e.g., speaking to people, attending social gatherings, eating or drinking in public, using public restrooms, public speaking), and patients are usually symptom-free when alone. If the fear is strictly confined to speaking or performing in public, a performance-only specifier is applied to the diagnosis. Common symptoms seen in social anxiety disorder include blushing, muscle twitching, and stuttering, in addition to other typical symptoms of anxiety. Panic attacks may also occur in either specific phobia or social anxiety disorder on exposure to the feared object or situation. However, social anxiety disorder is differentiated from panic disorder in that it involves the fear of scrutiny by others, rather than the fear of having a panic attack.

SPECIFIC PHOBIAS

Specific phobias are coded by one of five specifiers: animal (e.g., insects, dogs, spiders), natural environment (e.g., heights, water, storms), blood–injection–injury (e.g., blood, injury, medical procedures), situational (e.g., flying, bridges, elevators), or other.[1] Significant impairment of functioning or marked distress must be present for a diagnosis of specific phobia to be warranted. For example, fear of flying might constitute a diagnosis of specific phobia in a person whose job requires airplane travel, but it would not impair functioning in someone who never has occasion to fly.

First-line management of specific phobias involves avoidance of the stimuli or exposure-based psychotherapy, such as CBT or virtual reality exposure. Medications are not generally considered beneficial, as pharmacotherapy for specific phobia is largely understudied and psychotherapy is extremely successful. Benzodiazepines effectively reduce anxiety associated with a phobic trigger, but they may also interfere with the efficacy of these exposure therapies.[20,25,113]

Table 83-10

Symptoms of Social Anxiety Disorder (Social Phobia) (Items 1–5) and Specific Phobia (Items 2–5)[1]

1. Marked and constant fear of one or more social situations in which the person is exposed to unfamiliar people or possible scrutiny by others and the person fears humiliation or embarrassment
2. Experiencing the situation causes an immediate anxiety response
3. Feared situation is avoided or experienced with intense anxiety or distress
4. Feared situation exceeds the true risk associated with the social situation according to sociocultural norms
5. Fear or avoidance significantly interferes with the person’s normal routine or activities or causes marked distress

---

Social Anxiety Disorder

EPIDEMIOLOGY AND CLINICAL COURSE

In the United States, the lifetime and past-year prevalence of social anxiety disorder is approximately 13% and 7%, respectively.[14,124] The male-to-female prevalence ratio is approximately 2:3.[9] Social anxiety disorder usually begins early in life, with a mean onset between ages 14 and 16 years.[125] More than 50% of patients are affected before adolescence, and a history of shyness and behavioral inhibition throughout childhood is common.[125] Unless effectively treated, the clinical course is often chronic, unremitting, and lifelong, and only 20% to 40% of patients are reported to recover after 20 years of living with this condition.[124]

COMORBIDITY AND CLINICAL SIGNIFICANCE

Comorbidity in social anxiety disorder is high, with an estimated 70% to 90% of individuals having at least one other psychiatric disorder in their lifetime.[1,124,125] Common comorbid conditions include simple phobia, major depression, GAD, panic disorder, body dysmorphic disorder, and alcohol abuse. Because of its early onset, social anxiety disorder usually precedes the development of comorbid disorders. Alcohol is commonly used to decrease anxiety in social situations. The risk of suicide attempts is high, especially in those with both social anxiety disorder and another psychiatric illness, like depression.[9]

Because social anxiety disorder usually begins during the teenage years, it can seriously interfere with development of normal social skills, achievement of full academic and career potentials, and abilities to form interpersonal relationships.[126] This leads to functional disabilities that may persist for a lifetime. Social anxiety disorder is associated with unemployment, lower levels of education, and dependence on public financial support systems.[9] Persons with social anxiety disorder are less likely to marry, and more than half report moderate-to-severe impairments in their abilities to carry out ordinary daily activities.[126]

ETIOLOGY AND PATHOPHYSIOLOGY

Social anxiety disorder is a familial disease, but the relative contributions of genetic versus environmental influences have not been differentiated.[17] Early factors predisposing to its development include anxious behavior modeling in parents and parental overprotection.[1] Shyness in children, which is associated with later development of social anxiety disorder, has been linked to a specific genetic polymorphism of the serotonin transporter promoter region.[127]

Biologic studies suggest performance-only social anxiety disorder has a different underlying pathophysiology involving noradrenergic system dysfunction. Conversely, in nonperformance-only social anxiety disorder, there is substantial evidence for dopaminergic (decreased dopamine neurotransmission) and serotonergic dysfunction (5-HT type-2 receptor hypersensitivity).[128–130]

TREATMENT OF SOCIAL ANXIETY DISORDER

Early detection and treatment of social anxiety disorder are vital in reducing lifelong functional consequences and may prevent development of comorbid disorders. Because of the nature of the disorder, some sufferers are reluctant to seek treatment resulting in an average treatment delay of 16 years.[131] Those who seek help, even in psychiatric settings, are rarely diagnosed and treated appropriately.[125] Pharmacotherapy has become first line, but nonpharmacotherapy, particularly CBT, is also beneficial.[20] Data do not support the routine use of combined modalities in the management of social anxiety disorder; clinicians should determine whether combined therapy would be useful on a case-by-case basis.[132]

Selective Serotonin Reuptake Inhibitors and Serotonin and Norepinephrine Reuptake Inhibitors

As with other anxiety disorders, SSRIs, in addition to the SNRI venlafaxine, are considered the primary treatment option for most patients with social anxiety disorder[125] for which paroxetine, sertraline, fluvoxamine CR, and venlafaxine XR are FDA-approved.[132] Nonetheless, fluoxetine, citalopram, and escitalopram have also demonstrated efficacy in controlled clinical trials although fluoxetine has negative evidence as well.[20,132] Preliminary evidence with duloxetine suggests this agent may be useful.[133]

Unlike patients with GAD and panic disorder, those with social anxiety disorder often tolerate standard antidepressant starting doses. Target doses for social anxiety disorder are typically within the normal antidepressant dosage ranges. It is thought SSRIs exhibit a flat dose–response curve.[134] Fixed-dose studies of paroxetine (20, 40, and 60 mg/day) and duloxetine (≥60 mg/day) in social anxiety disorder found no overall difference in efficacy between doses.[133,135] Although some individuals may require higher dosages, adequate time (2–4 weeks) should be allowed before the dosage is increased. Response to SSRIs occurs gradually, and an adequate medication trial to assess response should last at least 8 to 10 weeks. Many who experience minimal response at week 8 may show a good response at week 12, and improvements have been found to continue throughout 16 weeks of treatment.[136]

Other Antidepressants

The MAOIs phenelzine (60–90 mg/day), tranylcypromine (30–60 mg/day), and selegiline (5 mg twice daily) have also demonstrated marked efficacy for social anxiety disorder but are reserved for SSRI nonresponders.[20,125,132]

Case reports and open studies suggest bupropion may be useful in treating social anxiety disorder, but controlled trials are needed to define its role.[125] Mirtazapine has conflicting evidence from small RCTs but may be considered in SSRI nonresponders.[20] Imipramine is ineffective for social anxiety disorder, and TCAs (except clomipramine) are not among the recommended treatment options.[20,125,132] Likewise, nefazodone is not recommended given the risk of hepatotoxicity and conflicting evidence, including one negative RCT.[20]

Benzodiazepines

Benzodiazepines are generally considered second-line therapy for social anxiety disorder, as they have limited efficacy in treating psychiatric comorbidities and abuse/dependence potential. In clinical practice, they are commonly used in combination with SSRI therapy on an as-needed basis before participation in stressful social situations.[132] However, the efficacy of adjunctive benzodiazepines to decrease time to response or increase response rate is unclear.[137] The high-potency benzodiazepines may be useful as monotherapy in select patients. Clonazepam (1–3 mg/day) was markedly efficacious in one controlled study, whereas alprazolam (1–6 mg/day) showed only modest efficacy compared with placebo.[132]

β-Blockers and Other Miscellaneous Agents

β-Adrenergic receptor blockers reduce peripheral autonomic symptoms of anxiety and, thus, are useful for performance-related social anxiety disorder.[125] Propranolol (10–80 mg) and atenolol (25–50 mg) are the two recommended agents and can be used on an as-needed basis (1–2 hours before the performance) to reduce performance anxiety symptoms such as tremors, palpitations, and blushing. A test dose should be tried before the actual occasion to assess tolerability.

Pregabalin is also considered to be an acceptable first-line agent, in the absence of comorbidities which would benefit from an SSRI, based on placebo-controlled trials for acute management and relapse prevention.[138] It appears a higher pregabalin dose (450–600 mg/day) may be necessary for effective treatment. Other anticonvulsants, antipsychotics, and miscellaneous agents have also been reported to be effective in the treatment of social anxiety disorder, but they are considered second- or third-line treatments.[20,43,132] These include gabapentin, tiagabine, topiramate, valproate derivatives, olanzapine monotherapy, adjunctive aripiprazole, adjunctive risperidone, and atomoxetine.

Nonpharmacologic Treatments

Several studies have demonstrated CBT to be comparable to medications in the treatment of social anxiety disorder.[139] Although medications may work faster, CBT is believed to result in longer-lasting treatment gains with effects persisting for 1 to 5 years. The cognitive therapy component changes maladaptive thought patterns, such as expectations of performing poorly and over concern about negative evaluation by others.[139] The behavioral therapy component, as in other anxiety disorders, involves repeated exposure and practice performing in those feared situations. Social skills training can also be beneficial in improving interpersonal communication skills.

CLINICAL PRESENTATION OF SOCIAL ANXIETY DISORDER

CASE 83-8

QUESTION 1: S.H., an 18-year-old man, is brought for psychiatric consultation by his mother who complains her son is extremely shy and she’s concerned about his ability to “fit in” at college. S.H. was referred to the psychiatrist by his primary-care physician, who reports S.H. is physically healthy. S.H.’s mother states he is a very bright young man who made straight as in high school despite frequent absenteeism. He only has one close friend and has never been on a date. S.H.’s mother says during high school, S.H. rarely attended school social functions and spent much of his time in his room working on his computer. On graduation from high school, he received a full scholarship to a community college but is quite anxious about going and is debating whether he should turn down the scholarship. When questioned by the psychiatrist, S.H.’s face turns bright red, and his voice shakes when he speaks. S.H. admits his behavior is not normal but says he is afraid he might “do something stupid” when he is around people and becomes extremely embarrassed when he has to talk to anyone. He has wanted to ask a certain girl on a date for 3 years but experienced severe anxiety attacks on the few occasions he tried to approach her. S.H. is afraid of being turned down and believes no girl would ever want to date someone like him. The psychiatrist’s diagnosis is social anxiety disorder. What clinical features of social anxiety disorder are present in S.H.?

S.H. exhibits many characteristic features of the generalized type of social anxiety disorder. S.H. admits he does not like being around people for fear of embarrassment, and he generally avoids social situations, which are classic traits of social anxiety disorder. Symptoms of blushing and shaking voice are also common in social anxiety disorder, as well as other typical anxiety symptoms such as palpitations, trembling, sweating, tense muscles, dry throat, hot/cold sensations, and a sinking feeling in the stomach. S.H. also displays hypersensitivity to rejection and low self-esteem, and he realizes his behavior and fears are unreasonable. These symptoms and S.H.'s young age are consistent with a diagnosis of social anxiety disorder.

S.H.'s case illustrates the substantial disability that can result from this illness. S.H.'s anxiety disorder has deprived him of normal social development, making friends, dating, participating in social functions regularly, and pursuit of higher education. Future impairments throughout S.H.'s life are likely to be significant unless his anxiety is treated successfully.

TREATMENT SELECTION FOR SOCIAL ANXIETY DISORDER

CASE 83-8, QUESTION 2: The physician decides to initiate sertraline 50 mg every morning for S.H. Is the prescribed pharmacotherapy appropriate in this case?

Because S.H.'s generalized social anxiety disorder is severely affecting his life, medication treatment is indicated. SSRIs are first-line therapy for treating social anxiety disorder, and sertraline is a good choice because it is FDA-approved for this indication and available as a generic. Although not applicable in this case, sertraline is also effective for many other psychiatric disorders commonly seen in patients with social anxiety disorder. The sertraline starting dose of 50 mg/day is appropriate for S.H., and 50-mg increment dosage increases can be made every 4 weeks according to response, up to a maximum of 200 mg/day. Signs of response may be seen within 2 to 4 weeks, but 8 to 12 weeks is usually required for optimal results. If available, CBT may also be combined with pharmacotherapy for S.H.

GOALS AND DURATION OF TREATMENT

CASE 83-8, QUESTION 3: What are the goals of treatment in this case, and how can S.H.'s response to treatment be objectively assessed? How long should effective therapy be continued?

Three principle domains of treatment outcomes have been defined for social anxiety disorder: symptoms, functionality, and overall well-being.[54] It is recommended that all three of these areas are assessed because even if all anxiety symptoms disappear, treatment is not clinically significant unless functioning also improves. The clinician-rated Liebowitz Social Anxiety Scale and the patient-rated Sheehan Disability Scale can be used for measuring improvements in symptom and functional ability domains, respectively.[54] In S.H.'s case, the desired outcomes of treatment include reducing fear and avoidance of social situations, enabling him to comfortably interact socially and attend college, and improving his quality of life.

Several studies have examined relapse rates after double-blind discontinuation of effective treatment in social anxiety disorder.[132,136,139] Long-term studies have shown sertraline, paroxetine, escitalopram, fluvoxamine CR, venlafaxine XR, pregabalin, and clonazepam prevent relapse of social anxiety disorder during continuation treatment.[20] Therefore, pharmacotherapy should be continued for at least 1 year after response.[125,132] After that time, a gradual medication discontinuation trial may be attempted with vigilant monitoring for signs of relapse.

POST-TRAUMATIC STRESS DISORDER AND ACUTE STRESS DISORDER

Diagnostic Criteria

PTSD and acute stress disorder occur in people who have experienced a severely distressing traumatic event. These disorders are

---

characterized by symptoms of intrusive re-experiencing, avoidance features, autonomic hyperarousal, and negative cognitions and mood symptoms.[1] In addition to war veterans, PTSD also occurs in persons exposed to events such as natural disasters, serious accidents, criminal assault, rape, physical or sexual abuse, and political victimization (refugees, concentration camp survivors, hostages). The trauma does not have to involve physical injury to the PTSD victim. Witnessing someone else being injured or killed, being diagnosed with a life-threatening illness, and experiencing the unexpected death of a loved one are common types of trauma that may lead to PTSD.[1]

Symptoms of PTSD are presented in Table 83-11.[1] According to diagnostic criteria, the person must have exposure to actual or threatened death, serious injury, or sexual violence via directly experiencing the event, witnessing the event in person, learning the event occurred to a close family member or friend, or experiencing extreme exposure to aversive details of an event.[1] Specifiers indicate whether PTSD is delayed (after 6 months) onset in relation to the trauma and/or whether it is associated with dissociative symptoms.[1] Symptoms must persist for at least 1 month to meet the criteria for PTSD. Acute stress disorder is a separate diagnostic category in the DSM-5 and refers to cases in which symptoms last less than 1 month (but at least 3 days).[1] It involves many of the same clinical features as PTSD, and like with PTSD, symptoms must be severe enough to interfere with functioning.

Epidemiology and Clinical Course

PTSD is associated with a lifetime prevalence in the general population of approximately 10% and up to 24% among deployed serviceman from Iraq and Afghanistan.[140] PTSD is twice as common in women, although overall, men are exposed to trauma more often.[141] Rates of PTSD are expected to rise as the frequency of traumatic events throughout the world continues to increase. An estimated 80% to 90% of individuals in the United States today will experience at least one event during their lifetime traumatic enough to lead to PTSD.[141]

Most people who are exposed to a traumatic event do not develop PTSD; approximately 90% of individuals experience a normal acute stress response to trauma and fully recover.[141] Risk factors for the development of PTSD include experiencing assaultive violence, more severe and chronic traumas, a history of depressive or anxiety disorders, lack of social support after the trauma, and experiencing dissociative or other intense symptoms during or soon after the trauma.[140–142] Previous exposure to trauma also increases the risk of developing PTSD after later traumas, and survivors of childhood sexual or physical abuse have been found to be especially vulnerable.[142,143]

Overall, 79% to 88% of PTSD patients also suffer from other disorders in their lifetime, including major depression, alcohol or other substance abuse, GAD, panic disorder, and phobic disorders.[140,141,143–145] The risk of suicidality in PTSD is high and likely influenced by comorbid major depression.[146] Recent studies have also found associations with PTSD and coronary heart disease, traumatic brain injury, and sexual dysfunction.[147–149] PTSD causes significant functional disability and has been associated with school failure, teenage pregnancy, unemployment, marital instability, legal problems, and impaired performance in the workplace.[150]

The course of PTSD is highly variable. Most patients who meet criteria for PTSD 1 month after trauma show spontaneous recovery within 6 to 9 months.[144] PTSD continues for years in a significant minority, estimated at 10% to 25%, and some sufferers experience a lifelong course of illness.

Etiology and Pathophysiology

Psychological trauma, especially that which occurs early in life or is chronic in duration, can cause persistent changes in various aspects of brain functioning and in neurobiologic responses to stress.[151] Evidence of altered NE, 5-HT, glutamatergic, GABA system, HPA axis, neuroendocrine, substance P, and opioid system functioning has been found in PTSD.[152–155] Stress-induced hyperactivity of central noradrenergic systems is believed to lead to the generalized anxiety and autonomic hyperarousal associated with PTSD.[153]

Neurobiologic consequences of stress and trauma result in both structural and functional changes in the brain, including reduced hippocampal volume and excessive activation of the amygdala.[156] Genetic factors may also play a role in influencing vulnerability to the damaging effects of stress.[157]

Table 83-11

Symptoms of Post-traumatic Stress Disorder for Individuals ê6 Years of Age[1]

1. Intrusion (e.g., memories, dreams, dissociative reaction (like flashbacks), intense distress that is experienced on exposure to stimuli associated with the traumatic event, or physiologic reactions to internal or external cues that reflect the event)
2. Avoidance (e.g., avoidance of or efforts to avoid distressing memories, thoughts, or feelings or external reminders such as places, people, conversations about or related to the event)
3. Increased arousal including at least two of the following:
    - Sleep disturbances
    - Irritability or anger outbursts
    - Difficulty concentrating
    - Hypervigilance
    - Exaggerated startle response
    - Reckless of self-destructive behavior
4. Persistent negative alterations in cognition or mood associated with the event including at least two of the following:
    - Amnesia surrounding the event
    - Negative beliefs or expectations about oneself, others, or the world
    - Distorted cognitions about the cause or consequence of the event where the individual blames themselves or others
    - Negative emotional state
    - Diminished interest or participation in activities
    - Detachment or estrangement
    - Lack of ability to experience positive emotions

Treatment of Post-traumatic Stress Disorder

Both medications and CBT are useful in treating PTSD. Nonpharmacologic therapies alone may be appropriate for initial treatment of mild PTSD, but pharmacotherapy, either alone or in some instances in combination with psychological therapies, may be recommended for patients with moderate or severe illness.[25,142,143,150,158] When assessing various treatment options for PTSD, it is important to consider effects on all four core symptom clusters (re-experiencing or intrusive symptoms, avoidance, hyperarousal, or negative cognitions and mood symptoms). Not all PTSD treatments are effective for each domain.

The preferred first-line medications in PTSD are SSRIs or the SNRI, venlafaxine

XR, but various other antidepressants may also be useful. Response to pharmacotherapy occurs very gradually, taking 8 to 12 weeks or longer. Partial response at 12 weeks of treatment may be followed by full remission after several more months of therapy; therefore, an adequate period should be allowed to fully determine response to a particular medication. Lack of improvement after 4 weeks of therapy indicates nonresponse, so alternative treatment strategies should be tried in these cases.[159] Although further research is needed, prevention of PTSD using various pharmacologic strategies has been evaluated in adults. A recent review highlights potential utility of hydrocortisone, but additional studies are needed.[160]

SELECTIVE SEROTONIN REUPTAKE INHIBITORS AND SEROTONIN AND NOREPINEPHRINE REUPTAKE INHIBITORS

Sertraline and paroxetine are currently the only FDA-approved SSRIs for PTSD. Large controlled studies have demonstrated that both agents, as well as venlafaxine, are effective and superior to placebo.[161] They also have beneficial effects on depression and general anxiety symptoms and have been associated with improvements in overall functioning and quality of life.[159,161] Use of fluoxetine also appears to be effective in treating PTSD in some patients, although study results have been mixed.[20,25] Citalopram, escitalopram, and fluvoxamine have shown efficacy in the treatment of PTSD in open trials, but randomized, double-blind, placebo-controlled studies have yielded negative results.[159,162] Finally, one small, naturalistic study in treatment-resistant men suggests duloxetine may be effective in managing comorbid depression and PTSD.[163] However, in another small, prospective study in military veterans suggests additional studies are warranted.[164]

OTHER ANTIDEPRESSANTS

Several open studies and case reports suggest nefazodone, mirtazapine, and bupropion are effective in treating core symptoms of PTSD.[155,165] Although supporting evidence for these antidepressants is not as strong, they may be considered appropriate alternatives to SSRIs or venlafaxine in certain patients. The TCAs amitriptyline and imipramine and the MAOI phenelzine have also been found to be effective for PTSD in controlled trials, but these agents are generally not recommended because of their poor tolerability and safety profiles.[143] Because of the relatively high risk of suicide in PTSD, TCAs can be especially dangerous in this population.

MISCELLANEOUS AGENTS

Various other medications have been used successfully in limited numbers of PTSD cases. Anticonvulsants carbamazepine, valproate, topiramate, tiagabine, gabapentin, oxcarbazepine, vigabatrin, pregabalin, levetiracetam, and lamotrigine have been studied with inconsistent results, mostly in case series and open-label trials.[20,25,161,165] These agents may be effective in certain patients and can be useful for reducing irritability, impulsivity, and anger or violent outbursts, particularly in patients with bipolar disorder.[166] Anticonvulsants may also be effective for intrusive, re-experiencing, and hyperarousal symptoms. Atypical antipsychotic agents (risperidone, quetiapine, olanzapine) have been used effectively to treat PTSD-related psychotic symptoms and sleep disturbances, though evidence is limited. One study failed to find benefit with adjunctive use of risperidone in treatment-resistant PTSD in military service personnel compared to placebo.[167] However, a recent meta-analysis suggests these agents may help target symptoms of intrusion.[168] The α_1-adrenergic antagonist, prazosin, may decrease nightmares, increase sleep time, and reduce other core symptoms in patients with PTSD.[155,169] Higher doses, up to 16 mg/day, may be needed to optimize efficacy.[170] Conflicting evidence exists for the use of the β-adrenergic antagonist, propranolol, which has been studied in blocking memory consolidation and therefore may prevent PTSD if administered within hours of the traumatic event.[171] Larger studies are needed to determine whether this is a useful preventive option. As previously mentioned, preliminary evidence supports the use of hydrocortisone for this indication, though additional studies are needed.[160] Benzodiazepines are generally ineffective in treating PTSD, and use of these agents is not recommended.[172]

NONPHARMACOLOGIC TREATMENTS

Various types of psychosocial therapies have been used in the treatment of PTSD, including anxiety management training to help patients cope with stress.[172] Trauma-focused CBT and eye movement desensitization and reprocessing treatment have both demonstrated effectiveness in PTSD, and either of these treatments are recommended for all patients with PTSD.[140,158] Cognitive therapies seem to be most effective for symptoms of demoralization, guilt, and shame, whereas exposure therapies are better for reducing intrusive thoughts, flashbacks, and avoidance behaviors. Studies are needed to further investigate the utility of virtual reality exposure therapy and transcranial magnetic stimulation in PTSD.[173,174] Trials of combined psychosocial therapies and medication are inconclusive and require further investigation to determine superior effectiveness compared with either treatment strategy alone.[175]

Clinical Presentation of Post-traumatic Stress Disorder

CASE 83-9

QUESTION 1: D.D. is a 42-year-old woman who was attacked and raped in the driveway of her home as she was getting out of her car 1 month ago. She did not seek medical treatment at the time and waited several days before reporting the incident to anyone, including her family. She presents to her physician complaining that she cannot sleep and she is irritable, anxious, and depressed. When asked about any recent stressors in her life, she finally tells her doctor about the rape. D.D. has no history of psychiatric illness, admits her symptoms have appeared since the attack, and says she has never had any psychiatric problems until now. She states she has nightly nightmares and becomes extremely anxious every time she comes home and gets out of her car at night (which she avoids doing when possible). She is startled when the phone rings or when someone approaches her unexpectedly, and she literally freezes if she sees a man who bears any physical resemblance to her attacker. D.D. also states that memories of the rape often flash through her mind for no reason, although she tries hard not to think about it. The assailant has not been caught, and D.D. feels extremely guilty for not promptly reporting the crime. Her symptoms are interfering significantly with her ability to work and have put a strain on her marriage. What clinical features of PTSD does D.D. display?

Individuals with PTSD often present with nonspecific complaints indicative of a generalized anxiety, depression, or substance use disorder. They may not realize or want to reveal an association between their symptoms and the trauma experienced. Careful evaluation by the clinician is required to elicit a pattern suggestive of PTSD. D.D. displays many target symptoms of PTSD, including re-experiencing/intrusive symptoms (nightmares, recurrent memories), avoidance of the activity reminding her of the trauma, symptoms of increased arousal (sleep difficulties, irritability, exaggerated startle response), and negative alterations in cognition (guilt). In addition, she is experiencing feelings of depression, distress, marital problems, and impairment in occupational functioning as a result of her symptoms. The lack of any previous psychiatric illness combined with the temporal relationship between the attack and her symptoms supports the presence of PTSD as opposed to another anxiety or depressive disorder. Since her trauma occurred 1 month ago, her condition would be classified as acute-onset PTSD.

Treatment Selection and Selective Serotonin Reuptake Inhibitor Dosing

CASE 83-9, QUESTION 2: What factors are important in the selection of an initial treatment for D.D.?

Because D.D. is exhibiting moderate-to-severe PTSD symptoms, pharmacotherapy is indicated. Medication treatment should be combined with CBT if it is available, but nonpharmacologic therapies alone are generally reserved for patients with mild symptoms. An SSRI is the preferred initial medication treatment for most patients.[161] Sertraline is an appropriate choice of treatment in this case and is FDA-approved for PTSD. Low initial SSRI doses are recommended in PTSD, so sertraline can be started at 25 mg/day and gradually increased to the target dosage range of 100 to 150 mg/day, according to response and tolerability.[165] Persistent sleep complaints during the first month after a traumatic experience may predispose the patient to chronic PTSD, so management of sleep disturbances is an important component of initial PTSD treatment.[175] If CBT for insomnia is available, this may be considered.[176]

Clinical Assessment and Goals of Therapy

CASE 83-9, QUESTION 3: What are the goals of treatment in this case, and how can D.D.'s symptoms be objectively assessed?

The first goal of treatment of PTSD is to reduce the core symptoms of re-experiencing/intrusion, avoidance, hyperarousal, and negative alterations in mood and cognitions. In D.D.'s case, these target symptoms include nightmares, intrusive memories, avoidance behaviors, irritability, hyperarousal, sleep difficulties, and guilt. Improvements should begin within the first 2 weeks and gradually continue over the course of 2 to 3 months. Secondary goals in this case include improving D.D.'s stress resilience, decreasing her work- and marriage-related disability, and improving her quality of life. Other general treatment goals in PTSD include decreasing detrimental behaviors (use of alcohol or substances, risky activities, violence) and treating comorbid psychiatric conditions.

Several different rating scales have been developed to assess response to treatments in PTSD.[54] The most commonly used clinician-rated scales are the Clinician Administered PTSD Scale and the Treatment Outcome PTSD Scale. The Clinician Administered PTSD Scale is most often used in clinical PTSD trials. The Sheehan Disability Scale is often used to assess functional impairment attributable to PTSD.

Course and Duration of Treatment

Good treatment response in PTSD is more likely to occur when treatment is started within 3 months of the trauma.[143,150] There is no well-established definition of response in PTSD, but a decrease in symptoms by 30% to 50%, along with substantial functional improvement, is commonly used in clinical trials. Full recovery during treatment of PTSD is fairly uncommon, and partial responders to either medication or psychosocial therapies may benefit from adding another treatment modality. When an initial SSRI trial is ineffective, the patient may be switched to another SSRI or another antidepressant shown to be effective in PTSD.[20] Partial responders may benefit from the addition of a second medication, depending on which core symptoms predominate (see Treatment of Post-traumatic Stress Disorder section).

For patients who respond, treatment should be continued for an additional 6 to 12 months for acute cases (when symptoms were present <3 months before treatment) and 12 to 24 months for chronic cases (when symptoms lasted >3 months before treatment).[143] Long-term SSRI treatment can prevent relapse of PTSD, especially in those who show good response during the first 3 months of therapy.[172] When pharmacotherapy is discontinued, it should be withdrawn gradually over the course of 1 to 3 months.

OBSESSIVE–COMPULSIVE DISORDER

Diagnostic Criteria

OCD is characterized by repetitive thoughts (obsessions) that cannot be ignored or suppressed voluntarily and/or repetitive behaviors (compulsions). The compulsions are designed to reduce anxiety associated with obsessions or to prevent some future event or situation; however, they are not actually connected to the obsessions in any realistic way or are excessive. Obsessions and compulsions result in marked distress, are time-consuming (greater than 1 hour/day), or significantly impair functional ability.[1] Both obsessions and compulsions are unpleasant and disturbing to the sufferer and are not associated with pleasure or gratification. This feature distinguishes OCD from certain other behaviors (e.g., excessive gambling or shopping) often described as "compulsive."

OCD is a clinically heterogeneous disorder involving a broad range of symptoms with four primary OCD symptom dimensions: symmetry obsessions and repeating, counting, and ordering compulsions; contamination obsessions and cleaning compulsions; hoarding obsessions and compulsions; aggressive, sexual, and religious and related compulsions. Although specific symptoms in an individual may change with time, they usually remain within the same dimension.[177]

Epidemiology and Clinical Course

OCD is one of the least common mood–anxiety disorders with a lifetime risk and 12-mo prevalence between 2% and 3%.[14] Although onset of illness ranges from very early childhood to adulthood, the mean onset of illness is 20 years, which is later than most anxiety disorders. Men tend to have an earlier onset of illness (childhood) than women (adulthood). Approximately one-fourth of patients experience symptoms by age 14, and onset after 30 years of age is rare.[1] Childhood onset OCD may be a distinct illness subtype.[177] There is usually a gradual onset

---

of symptoms, although abrupt onset may occur during stressful periods and pregnancy.[1,178]

The course and severity of OCD are highly variable and unpredictable. The majority of patients with OCD will have a chronic course that waxes and wanes rather than an intermittent or episodic course. Less than 10% of patients will have a deteriorating course.[179] A 40-year naturalistic study found that although 83% of patients were improved at the end of the follow-up period, only 20% experienced full remission.[179]

OCD can have seriously detrimental effects on function such as abilities to socialize, study, work, make friends, and maintain good relationships with family and friends given the time spent obsessing and performing compulsions as well as avoiding situational triggers.[1,180] It is estimated that each person with OCD loses an average of 3 years' wages during his or her lifetime.[180] Quality-of-life ratings in OCD patients indicate marked impairments and are similar to those observed in patients with depression.

Although several effective treatments are currently available for OCD, there is an average delay of 7.5 years between onset and seeking medical evaluation for OCD.[180] This may be because most OCD patients realize their symptoms are senseless, so they attempt to hide their disorder because of embarrassment. People with OCD often carry out their rituals privately and may be very successful at concealing their symptoms from others. Initial treatment for OCD is commonly sought outside psychiatric settings, and the obsessive–compulsive symptoms are often missed. Clinicians across the healthcare system can incorporate four simple OCD screening questions into their practice to improve detection: Do you have to wash your hands over and over? Do you have to check things repeatedly? Do you have recurrent distressing thoughts you cannot get rid of? Do you have to complete actions again and again or in a certain way?[181]

Psychiatric Comorbidity and Obsessive–Compulsive Spectrum Disorders

Identification of comorbid conditions with OCD is important because it can influence treatment decisions. As with other anxiety disorders, OCD is often accompanied by psychiatric comorbidity in 60% to 90% of patients with affective (e.g., depression, bipolar disorder), anxiety, and tic disorders being common.[1,20,25,179] Tics occur in 20% to 30% of OCD patients. These individuals believed to represent a distinct subtype of illness where patients are more likely to be male, have an earlier onset (before age 10 years), experience more severe symptoms, and have a poorer response to SSRIs than those with OCD alone.[182] Distinguishing from obsessive–compulsive personality disorder (OCPD), a personality pattern characterized by rigid and inflexible preoccupation with rules, lists, order, and perfectionism, can be difficult, and the two disorders co-occur in a small percentage of patients. OCPD, however, does not involve distressing obsessions and compulsions.

OCD is no longer classified as an anxiety disorder in the DSM-5 but rather an illness within a new obsessive–compulsive and related disorders.[1] Other related disorders included are body dysmorphic disorder (preoccupation with an imagined or slight defect in appearance), trichotillomania (recurrent impulses to pull out one's hair), excoriation disorder (skin-picking), and hoarding disorder. Like OCD, many patients with these conditions have shown good response to treatment with serotonergic antidepressants such as clomipramine and SSRIs.[183]

Etiology and Pathophysiology

Since OCD displays such clinical heterogeneity, there may be several distinct etiologies for different subtypes of illness. Structural and functional brain imaging suggests that OCD is a neurologic disorder characterized by a hyperfunctioning circuit involving the frontal lobe and basal ganglia regions termed the frontostriatal circuit.[177] Abnormalities therein imply potential dysfunction in glutamatergic, dopaminergic, and serotonergic neurotransmission. In support of this hypothesis, these abnormalities normalize after successful treatment of OCD with SSRI monotherapy and antipsychotic augmentation. Preliminary evidence with glutamatergic agents suggests a role in treatment. Furthermore, neuromodulation therapies (e.g., deep brain stimulation, cycloserine-enhanced CBT) and neurosurgical techniques interrupting this circuit are often effective in the treatment of OCD. Aberrant activity in this system may lead to impaired executive function, decision-making, and memory as these cognitive domains are mediated by this system.

Besides biologic factors, twin and family studies support genetic influences, particularly in early-onset OCD cases.[17,184] Genetic studies have found associations between OCD and specific polymorphisms in the glutamatergic (high-affinity neuronal/epithelial excitatory amino acid transporters), dopaminergic (catechol-O-methyltransferase and dopamine D_4-receptor genes), and serotonergic (5-HT type 1Dβ and 5-HT type 2A receptor genes) pathways.[185–187] The heritability of OCD is estimated at 40% with the remaining variation purportedly mediated by environmental factors (e.g., perinatal events, trauma, stress, neuroinflammation).[177] An example of this is the autoimmune disease, called PANDAS (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection). Reports describe children who developed sudden and severe tics and obsessive–compulsive symptoms after strep throat infections.[188] These children may be better treated with other medications and modalities (e.g., antibiotics, corticosteroids, surgery). The possibility of a PANDAS correlation should be considered in any child who develops abrupt onset of obsessive–compulsive symptoms and has a history of pharyngitis within the past 6 months.

Treatment of Obsessive–Compulsive Disorder

Both medications and behavioral therapies are effective in the treatment of OCD. Behavioral therapy is vitally important for OCD, and the combination of drugs plus behavioral therapy provides optimal treatment. All medications consistently effective as monotherapy are potent inhibitors of serotonin reuptake. These include the SSRIs, clomipramine, and the SNRI venlafaxine.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS AND SEROTONIN AND NOREPINEPHRINE REUPTAKE INHIBITORS

SSRIs are the only first-line medication treatments for OCD of which fluvoxamine, fluoxetine, paroxetine, and sertraline are FDA-approved based on double-blind, placebo-controlled studies.[189] Citalopram and escitalopram also are effective but with less evidence to support their use, particularly with the former. No single SSRI is considered to be more effective than the others in treating OCD, but some patients may respond to or tolerate one agent better than another.[189] Usual SSRI starting dosages can be used in OCD, but at least 4 weeks should be allowed before exceeding the targeted minimally effective dosages (fluvoxamine 200 mg/day, fluoxetine 40 mg/day, paroxetine 40 mg/day, and sertraline 100 mg/day).[189] SSRIs are generally considered to have a dose–response relationship such that higher SSRI doses may be required to effectively treat OCD.[25] Additionally, several controlled studies support the efficacy of venlafaxine in the treatment of OCD.[190] Although other SNRIs (duloxetine, desvenlafaxine, milnacipran, or levomilnacipran) may ultimately show efficacy in the treatment of OCD, no well-controlled studies have been conducted evaluating these medications in OCD.[191]

CLOMIPRAMINE

Clomipramine was the first drug FDA-approved for OCD treatment and was considered the standard treatment for several years until the SSRIs gained popularity. Many large well-controlled studies have documented that clomipramine is superior to placebo and significantly improves OCD symptoms in approximately 60% to 70% of patients.[179,190] Clomipramine is the only TCA recommended for OCD treatment as others have not proven efficacious[20,25,113,179,192] although there is some evidence to the contrary.[193] This is attributed to its more potent effects on 5-HT reuptake inhibition compared with other TCAs. Clomipramine is often referred to as a SRI (serotonin reuptake inhibitor), not a SSRI (selective serotonin reuptake inhibitor), because its major active metabolite, desmethylclomipramine, is a potent inhibitor of NE reuptake. Clomipramine also blocks adrenergic, histaminergic, and cholinergic receptors resulting in an adverse effect profile similar to other TCAs (see Chapter 86, Depression).

Although direct comparison studies have shown clomipramine to be similar in efficacy to various SSRIs in treating OCD, several meta-analyses have concluded clomipramine is superior to SSRIs overall.[190,194] Nonetheless, clomipramine is currently reserved as a second-line treatment option for patients who do not respond adequately to SSRI/venlafaxine therapy given its poorer tolerability (e.g., sedation, orthostatic hypotension, and anticholinergic side effects).[190] Details about the clinical use of clomipramine are discussed in Case 83-11, Questions 1.

AUGMENTATION STRATEGIES

Other than venlafaxine, no other miscellaneous agents studied in OCD have demonstrated impressive efficacy as monotherapy. However, several agents appear to be useful as augmentation therapy to boost response to SSRIs or clomipramine in partial responders.[195] The combination of an SSRI plus clomipramine is one such option for patients who show partial response, although attention must be paid to potential drug interactions, which may lead to clomipramine toxicity (see Case 83-11, Questions 2 and 3).

Antipsychotic agents are the most studied pharmacologic augmentation strategy in OCD and may improve response in 30% of patients.[196] They may be particularly effective in four scenarios: treatment-refractory OCD, OCD with poor insight (often treatment refractory), comorbid tic disorders, and comorbid schizophrenia.[197] Several meta-analyses have been conducted on antipsychotic effectiveness.[196,198–200] Risperidone (0.5–4 mg/day) is generally considered to have the highest evidence base for antidepressant augmentation in OCD. Other reasonable agents include aripiprazole and haloperidol (of which haloperidol is less tolerated compared to second-generation antipsychotics). Conversely, quetiapine (up to 600 mg/day) and olanzapine (2.5–20 mg/day) use is controversial based on inconsistent evidence supporting their use in well-designed trials. Preliminary evidence suggests paliperidone may not be more effective than placebo, and ziprasidone may be less effective than quetiapine.[201,202] Recent evidence suggests antipsychotics are less effective than augmenting with CBT with exposure–response prevention (ERP) and, thus, may not be a preferred augmentation strategy.[203,204] Additionally, the use of antipsychotics must be weighed against tolerability and safety concerns such as metabolic dysfunction and extrapyramidal symptoms.

Anticonvulsants (e.g., topiramate, lamotrigine, pregabalin, gabapentin) may also be considered as augmentation agents although the evidence is limited to lower quality studies.[20,205] As such, this strategy should be one of last resort unless otherwise clinically indicated.

MISCELLANEOUS AGENTS

Benzodiazepines, although typically useful in other anxiety disorders, are generally not beneficial in treating OCD. There are several reports of clonazepam being effective as adjunctive therapy or monotherapy which may be explained by its serotonergic properties; however, double-blind placebo-controlled trials have been negative.[206] As such, clonazepam is not recommended by treatment guidelines.[179]

The MAOI phenelzine was one of the first medications studied for OCD. Early case reports of its use were favorable, but more recent findings suggest phenelzine is largely ineffective for OCD.[179]

NONPHARMACOLOGIC TREATMENTS

Cognitive Behavioral Therapies

CBT is an extremely important component of OCD treatment and should be incorporated into the treatment plan whenever possible. The combination of psychotherapy and medication is generally superior to pharmacotherapy alone but not to CBT alone.[20,179] CBT alone may be appropriate for mild OCD or in cases in which it is desirable to avoid medication (e.g., pregnancy, medical conditions). Treatment gains achieved with CBT often are maintained long after its discontinuation, which is an advantage versus pharmacotherapy, likely improving relapse prevention.[181]

The cognitive therapy component of CBT is aimed toward changing the detrimental thought patterns in OCD and is most helpful for obsessions such as scrupulosity, moral guilt, and pathologic doubt. The behavioral therapy aspect, ERP, involves exposure to feared objects or situations followed by prevention of the usual compulsive response. This type of therapy is most beneficial for patients with contamination fears, hoarding, and rituals involving symmetry, counting, or repeating. Because ERP is anxiety provoking and can be very distressing, patients may refuse to participate.[207]

Neurosurgery

Neurosurgical treatment of OCD has been practiced since the 1950s and is considered an option of last resort in treatment-refractory patients. Anterior cingulotomy and anterior capsulotomy are the most commonly used surgical procedures. Indications for neurosurgery include severe disability from symptoms and failed treatments (drugs and behavioral therapies) that have been tried systematically for at least 5 years.[208] Neurosurgery success rates range from 35% to 70%, complications (including potential infections, personality changes, cognitive impairment, and epilepsy) appear to be rare, and limited long-term follow-up studies indicate the benefit is maintained with mild-to-moderate impairments in neuropsychological performance.[208,209] Deep brain stimulation involving bilateral electrode implantation into the subthalamic nucleus and nucleus accumbens is gaining popularity for treatment-refractory OCD. Although this procedure is still experimental, overall preliminary results are positive.[210]

Defining Response to Therapy

Response to medication treatment in OCD is gradual and often delayed. Initial improvements usually begin to appear within the first month. Patients with unsatisfactory response by weeks 4 to 9 should have their SSRI dosages gradually increased to the manufacturer’s recommended maximum. A trial of 8 to 12 weeks at maximal tolerated medication dosages is recommended before assessing therapeutic benefit and maximal response may take as long as 5 to 6 months..

Since complete elimination of symptoms is rare with current treatments, the primary goal of OCD treatment is to minimize functional impact of symptoms.[211] Most clinical trials in OCD define clinical response as a 25% to 35% reduction in Yale–Brown

Obsessive–Compulsive Symptom Checklist (Y-BOCS) scores. Therefore, even those classified as responders may be left with 65% to 75% of their original symptoms, and this may or may not result in significant improvements in functioning or quality of life. The Y-BOCS is an objective tool in the initial evaluation of those who present with symptoms of OCD. It is a 10-item scale with a maximal possible score of 40; a score of more than 15 is generally considered to represent clinically significant obsessive–compulsive symptoms.[212] This scale is a standard tool for evaluating drug efficacy in OCD clinical trials and is often used in clinical practice to assess response to treatments with a version designed for administration with children.

STRATEGIES FOR MANAGING NONRESPONSE AND PARTIAL RESPONSE

Approximately 40% to 60% of patients show clinically meaningful improvements during an initial (SSRI or clomipramine) medication trial, but only a small percentage exhibit marked response.[190] Predictors of poor response include poor insight; hoarding, sexual, religious, and symmetry dimension symptoms; prepubertal onset of illness; and presence of comorbid personality, mood, or eating disorders.[20] For nonresponsive patients, it is usually recommended to pursue a second SSRI trial, as approximately 20% of initial nonresponders will respond with a subsequent trial. Given this and tolerability concerns, clomipramine is typically reserved as a third-line treatment option, although its use second line would be reasonable given its efficacy in SSRI nonresponders.[181,190] Patients with partial response to an initial SSRI trial may be better served by adding an augmentation agent to preserve therapy benefits rather than switching to a new medication and risk losing any improvement already gained. Additionally, using SSRI doses beyond those FDA-approved may be beneficial for poor responders if tolerability is acceptable.[213–215]

Clinical Presentation and Assessment

CASE 83-10

QUESTION 1: R.G. is a 25-year-old woman whose husband complains she spends 1.5 hours a day cleaning the stove and takes four showers each day. The unusual behavior began about 1 year ago after the birth of their son but has continued to worsen, and R.G.’s husband states that he cannot deal with her “odd habits” any longer. R.G. recently lost her job as a secretary because of tardiness (it took her 3 hours to get ready for work) and spending too much time away from her desk in the ladies' room. R.G. admits that it is silly, but she has irresistible urges to make sure both she and her surroundings are completely free of germs so her child will not get sick. She also confines herself to one floor of their three-level house because she is afraid she will fall down the stairs while carrying her son. R.G. also states that she constantly has "what if" thoughts about horrible things happening to her family, which are very disturbing. The physician's diagnosis is OCD. What clinical features of OCD does R.G. display, and how can her symptoms be objectively evaluated?

R.G. displays many characteristic symptoms of OCD. The most commonly encountered clinical presentation of OCD involves excessive fear of contamination with dirt, germs, or toxins and repeated washing of hands or cleaning objects or surroundings. These persons also typically avoid touching possibly dirty objects (e.g., doorknobs, money) or shaking hands with people. Another common clinical presentation of OCD is the patient with pathologic doubt who constantly worries something bad will happen because of his or her negligence. Individuals can be afraid they have failed to lock the door, turn off the stove, shut the refrigerator door, or secure the medicine cabinet from children. As a result, they continuously check and recheck their actions.

R.G. displays obsessions of contamination and pathologic doubt, and compulsions of excessive cleaning and washing. These symptoms are time-consuming, cause significant distress, and have led to her unemployment and marital difficulties. As seen in this case, most persons present with a mixture of various obsessions and compulsions. R.G. also realizes her thoughts and behaviors are "silly," which most often is the case in OCD. This case also illustrates the onset of OCD during times of stressful or significant life events. Pregnancy, death of a relative, and marital discord have been identified as precipitating factors in the onset of OCD.[178,211,216]

Selective Serotonin Reuptake Inhibitor Treatment of Obsessive–Compulsive Disorder

CASE 83-10, QUESTION 2: On assessment, R.G.'s Y-BOCS score is found to be 33. Her physician prescribes fluvoxamine and instructs R.G. to take 100 mg every morning for 1 week and then 200 mg every morning thereafter. He also refers R.G. to a psychologist to receive CBT. Is this initial choice of therapy appropriate?

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Selection and Dosing

SSRIs such as fluvoxamine are considered the best choice of initial pharmacotherapy for OCD. The primary differences between SSRIs involve pharmacokinetic properties and potential for drug interactions (see Chapter 86, Depression). Because there are no overall differences in SSRI efficacy, fluvoxamine is a suitable selection for R.G. However, the prescribed dosing instructions for R.G. are not appropriate. The initial recommended dosage for fluvoxamine in adults is 50 mg/day (25 mg in children), and it is best taken in the evening because it tends to be sedating. Using higher-than-necessary dosages can increase both adverse effects and medication costs, and these factors can lead to early termination of therapy. The dosage can be increased by 50-mg increments every 3 to 4 days according to patient tolerability, up to the initial targeted dose of 200 mg/day and a maximum of 300 mg/day.[189] Daily doses exceeding 100 mg should be given in two divided doses if once-daily dosing is not well tolerated.

ADJUNCTIVE COGNITIVE BEHAVIORAL THERAPY

R.G.’s Y-BOCS score of 33 indicates a moderate-to-severe symptom severity, which supports using a combined treatment approach. The overall efficacy of these nonpharmacologic treatments is estimated to be 50% to 70% when used alone, and their use to complement pharmacotherapy is considered vital.[181] For R.G., ERP therapy might involve covering her hands with dirt and not allowing her to wash them for a certain time period. These behavioral techniques cause extreme anxiety and discomfort, which often lead to dropout from therapy or noncompliance with “homework assignments” (which involve continuation of the therapy principles outside the clinical setting), but are highly effective if the patient can adhere to treatment.

SELECTIVE SEROTONIN REUPTAKE INHIBITOR ADVERSE EFFECTS AND PATIENT COUNSELING

CASE 83-10, QUESTION 3: What patient counseling information should be provided to R.G. in conjunction with the prescribed treatments?

All OCD patients beginning treatment should be counseled that medication response occurs gradually and several weeks may elapse before beneficial effects become noticeable. It is important to emphasize that maximal response may take 3 months or longer and complete elimination of all symptoms is unlikely. Inform patients that a variety of other medications exist for those who do not respond adequately to an initial trial.

R.G. should be educated about possible fluvoxamine side effects, including nausea, sedation or insomnia, and headache. Medication should be taken with food to decrease these effects. Side effects are most common during the initial weeks of therapy, are usually dose-related, and often subside with continued treatment. Other aspects of SSRI therapy, including additional adverse effects and their management and drug–drug interactions, are discussed in Chapter 86, Depression. Patients should be encouraged to report any problems to their treatment provider. The importance of adhering to prescribed therapies, both pharmacologic and behavioral, should also be stressed.

CASE 83-10, QUESTION 4: After 4 weeks, R.G. is taking fluvoxamine 200 mg daily and tolerating the medication well. She complains she has not noticed much improvement, and her Y-BOCS score is slightly decreased at 30. R.G. has been to the cognitive behavioral therapist twice but is reluctant to return because the therapy was so stressful. R.G. requests to be switched to a more effective medication, and she also asks to be given some alprazolam to help calm her anxiety during behavioral therapy sessions. What is the best course of action for R.G. at this point?

Switching to another medication is not recommended at this point because not enough time has elapsed to assess fluvoxamine's efficacy. R.G. is tolerating fluvoxamine well and has shown a mild improvement, so this medication should be continued for at least another 4 weeks. Additional counseling information should be provided to R.G. to emphasize this fact. An increase in fluvoxamine dosage, up to 250 or 300 mg/day, may be considered after several more weeks because some patients may respond better to higher dosages. If R.G.'s symptoms continue to cause significant functional impairment after 10 to 12 weeks of higher-dose fluvoxamine therapy, a change in treatment (e.g., switching to another SSRI or augmentation therapy) will be indicated.

R.G. should be encouraged to continue CBT to optimize the chance for successful treatment. An anxiety response is integral to the therapeutic benefits of behavioral therapies; because benzodiazepines can blunt this response, they may reduce their efficacy. Therefore, alprazolam should be avoided, and a temporary reduction in the intensity of behavioral therapy may be indicated instead. Fluvoxamine can also inhibit the CYP3A4-mediated metabolism of alprazolam, resulting in more pronounced effects from a given dose.

Course and Duration of Therapy

CASE 83-10, QUESTION 5: After 5 months of treatment, R.G. is happy to report her OCD is much improved (Y-BOCS score of 11). She still has intermittent obsessions related to contamination and doubting, but they are less intense than before. She is usually able to resist urges to clean and wash excessively and is using the stairs in their home with only mild discomfort. Her previous employer has agreed to let her return to her secretarial position when she is ready, and she plans to do so soon. R.G.'s husband is extremely pleased with her progress. Their primary question at this visit is whether treatment can be discontinued now because R.G. is doing so well. What recommendations should be provided regarding the long-term course of therapy for R.G.?

This case illustrates a common outcome of OCD treatment, in which some symptoms persist (as evidenced by a Y-BOCS score of 11), but significant improvements in functioning occur. It is currently recommended that effective treatment for OCD be continued for at least 1 year after response to reduce the risk of relapse.[212,217] Therefore, continued drug treatment for at least 7 more months is indicated. Results from several studies suggest decreased medication doses (with SSRIs and clomipramine) during maintenance therapy are comparably as effective as full doses in preventing relapse.[212] If R.G. was experiencing any fluvoxamine-related problems, a decrease to the minimally effective dose (150 mg/day) during maintenance therapy might be recommended.

After a 1-year maintenance period, discontinuation of medication may be considered by carefully weighing the possible risks and benefits. When medication therapy for OCD is withdrawn, the dosage should be gradually decreased by approximately 25% every 1 to 2 months. Continuous monitoring for signs of relapse is required during this period. Gradual discontinuation also lessens the chance of the withdrawal syndrome often occurring after abrupt discontinuation of SSRI or TCA therapy (see Chapter 86, Depression). Long-term or even lifelong maintenance pharmacotherapy is usually recommended after two to four severe relapses or three to four less severe relapses.

Clomipramine Treatment

DOSING GUIDELINES

CASE 83-11

QUESTION 1: K.T. is an 18-year-old Asian man who was diagnosed with OCD 2 years ago and also suffers from moderate depression. His physician plans to start him on clomipramine therapy because he has failed previous trials with paroxetine and fluvoxamine. Is clomipramine an appropriate choice of therapy for this patient? What recommendations can be made regarding initiation of clomipramine treatment?

Current guidelines recommend clomipramine be reserved for OCD patients who fail at least two SSRI trials; therefore, its choice for this patient is appropriate.[179] One precaution relevant to this case is that clomipramine, like other TCAs, is highly dangerous in overdose situations. Because K.T. is depressed, he should be evaluated carefully for any suicidal thoughts before starting clomipramine. If suicidal ideation is detected, it would be preferable to try another SSRI. This case also illustrates the common comorbidity of depression with OCD. Fortunately, most effective treatments for OCD are antidepressants, and drug treatment can be beneficial for both conditions. Nevertheless, the responses of depression and OCD to treatment are independent of one another, so depression may respond completely to a certain medication while OCD symptoms persist.[212]

Clomipramine should be initiated at a low dosage of 25 to 50 mg/day administered with meals. Divided daily doses are sometimes used initially to minimize side effects, but the total daily dose can be given at bedtime after dose titration given its average elimination half-life of 24 hours.[189,218]

The clomipramine dosage should be increased to an initial target range of 150 to 200 mg/day during 2 to 4 weeks, guided by patient tolerability. The maximal recommended daily dosage of clomipramine is 250 mg/day because of the sharply increased risk of seizures (2.1%–3.4%) with higher dosages as compared with the risk with dosages less than 250 mg/day (0.24%–0.48%).[219] Longer duration of clomipramine therapy may also increase the risk of seizures. As such, use with caution in persons with a

history of seizures, head injury, or other factors might lower the seizure threshold.

Side Effects and Monitoring Guidelines

CASE 83-11, QUESTION 2: What guidelines should be recommended for monitoring the outcomes (both therapeutic and adverse) of clomipramine therapy?

Clomipramine is less well tolerated than the SSRIs and can cause a number of significant adverse effects, especially during the first few weeks of therapy. The most common side effects, reported in more than half of those taking clomipramine, include sedation, dry mouth, dizziness, and tremor.[219] Constipation, nausea, blurred vision, insomnia, and headache also occur frequently. K.T. should be advised these usually subside with continued treatment.

Many patients receiving long-term clomipramine (and other TCA) therapy gain substantial amounts of weight. As with the SSRIs, sexual dysfunction can be a problem in both men and women. In men, clomipramine can cause ejaculation abnormalities, which can impair fertility. Patients taking clomipramine should also be counseled about the additive CNS depressant effects with alcohol and to be cautious about the possible sedative effects while driving or performing other potentially hazardous activities.

As with other TCAs, an ECG should be performed before starting clomipramine in individuals at risk for heart disease and in pediatric patients. Elevations in liver enzymes have been observed frequently during the first 3 months of clomipramine treatment, and baseline liver function tests should also be obtained before initiating treatment. The liver enzyme changes are reversible on discontinuation of clomipramine therapy.

No therapeutic range for plasma drug concentrations has been firmly established for clomipramine in OCD, but monitoring plasma levels may be clinically useful in certain patients to guide dosing and minimize drug toxicity. Clomipramine metabolism exhibits interpatient variability, and it is difficult to accurately predict the resulting clomipramine level from any given dose. The initial hepatic metabolism of tertiary TCAs such as clomipramine involves demethylation through various isozymes, including CYP1A2, CYP2C19, and CYP3A4.[218,220] Both the parent drug (clomipramine) and the primary active metabolite (N-desmethylclomipramine) then undergo CYP2D6-mediated hydroxylation. Therefore, the metabolism of clomipramine will be affected by combination with any agent inhibiting CYP1A2, CYP2C19, CYP3A4, or CYP2D6. Clinically significant drug interactions are possible with several of the SSRIs, including fluoxetine, paroxetine, fluvoxamine, and sertraline (see Chapter 86, Depression).

Although various studies have failed to find a correlation between clomipramine plasma level and clinical response, the ratio of clomipramine to N-desmethylclomipramine may be important.[221] Clomipramine is primarily serotonergic, whereas N-desmethylclomipramine is more noradrenergic; higher levels of N-desmethylclomipramine relative to clomipramine have been associated with poorer clinical response. Factors impairing the CYP2D6-mediated elimination of N-desmethylclomipramine (e.g., concurrent medications that are potent CYP2D6 inhibitors and CYP2D6 poor metabolizers) may possibly decrease the efficacy of clomipramine by shifting the metabolic ratio in an undesired direction.

Asian patients such as K.T. have been found to have significantly decreased clearance of clomipramine and higher clomipramine to N-desmethylclomipramine ratios compared with whites, which may necessitate use of lower doses.[222] This is probably caused by a genetic polymorphism of either CYP2C19 or CYP2D6, which results in decreased metabolic capacity via these metabolic pathways in the Asian population. Careful monitoring for possible signs of toxicity should accompany dose increases, and the clomipramine plasma level should be checked in those patients (Asian or otherwise) who show unexpected effects with usual doses. An opposite effect has been described in ultra-rapid CYP2D6 metabolizers, in which unusually high clomipramine dosages may be required for therapeutic efficacy.

Augmentation

CASE 83-11, QUESTION 3: After 10 weeks of taking clomipramine 100 mg at bedtime, K.T. has shown partial response. He continues to experience mild-to-moderate anticholinergic side effects and frequent daytime fatigue. His plasma clomipramine level is relatively high for the given dose at 453 ng/mL (clomipramine plus desmethylclomipramine; range 150–450 ng/mL).[223] The physician decides to add another drug to augment treatment. Considering K.T.'s current medication regimen and the evidence supporting the different augmentation strategies, which drug would be the best choice for K.T.?

When adding an SSRI to a TCA, the potential for drug interactions should always be considered. Clomipramine is metabolized by CYP1A2, CYP3A4, CYP2C19, and CYP2D6.[218,220,224,225] The CYP2D6 pathway is particularly important because it is the rate-limiting metabolic pathway for elimination of both clomipramine and desmethylclomipramine. Fluvoxamine, paroxetine, and fluoxetine are all strong inhibitors of clomipramine metabolism, whereas sertraline is a weak–moderate inhibitor. Alternatively, escitalopram and citalopram would not be likely to cause a significant drug interaction, but evidence for escitalopram as an augmenting agent in combination with clomipramine is lacking.[226] A combination less likely to be associated with a drug interaction is the combination of clomipramine and a second-generation antipsychotic; however, most trials combined antipsychotics with SSRIs rather than clomipramine. Nonetheless, antipsychotic augmentation with agents demonstrating more consistent efficacy in well-designed trials (e.g., risperidone and aripiprazole) is a reasonable strategy in patients requiring more improvement as previously discussed. Haloperidol would not be the optimal choice in K.T. because it inhibits clomipramine metabolism, and as a first-generation antipsychotic, it is associated with numerous side effects. Unfortunately, most of the well-designed studies are often small (15–45 patients).

Sleep Disorders

Devon A. Sherwood and Anna K. Morin

CORE PRINCIPLES

	CORE PRINCIPLES	CHAPTER CASES
	INSOMNIA AND RESULTING DAYTIME SLEEPINESS	
1	Asking the right questions to investigate the type of insomnia (i.e., trouble falling asleep, staying asleep, or early morning awakening), possible causes (lifestyle issues, drugs), resulting impairment, and concomitant conditions are essential to determine proper management.	**Case 84-1 (Questions 1, 2)** **Table 84-1, 84-4,** **Figure 84-2**
2	Nonpharmacologic treatments such cognitive-behavioral interventions are recommended first-line therapy for managing insomnia in a variety of patients owing to high efficacy and avoidance of medication side effects.	**Case 84-1 (Questions 3, 4)** **Table 84-2**
3	Pharmacologic treatments for insomnia are selected based on their efficacy, tolerability, onset and duration of effect, potential for next-day hangover, and abuse potential.	**Case 84-1 (Questions 5–10)** **Table 84-3**
4	Insomnia concurrent with medical illness is frequently chronic (>1 month) and, if left untreated, may affect recovery from the medical condition. Treating both conditions at the same time is recommended.	**Case 84-2 (Questions 1–4)** **Table 84-5,** **Figure 84-2**
5	Insomnia concurrent with psychiatric illness requires optimization of psychiatric maintenance medications and the judicious use of hypnotic medications based on type of sleep complaint and substance abuse history.	**Case 84-3 (Questions 1–4)** **Figure 84-2**
6	Managing insomnia in an elderly individual involves consideration of age-related pharmacodynamic and pharmacokinetic changes and counseling regarding realistic treatment expectations. Medication doses lower than those used in younger individuals should be prescribed.	**Case 84-4 (Questions 1–5)** **Table 84-3**
7	If nonpharmacologic treatment is ineffective, diphenhydramine is considered safe for short-term use (<1 week) in pregnancy. Risks outweigh benefits for benzodiazepines and nonbenzodiazepine receptor agonists in pregnancy.	**Case 84-5 (Question 1)**
	SLEEP APNEA	
1	Sleep apnea leads to excessive daytime sleepiness, fatigue, and increased risk of cardiovascular and cerebrovascular disease. Effective	**Case 84-6 (Questions 1, 2)**

treatment with continuous positive airway pressure or surgical interventions can decrease cardiovascular disease and improve overall functioning and quality of life.	
② It is essential to avoid sedating medications in patients with sleep apnea because these agents interfere with mini-arousals that keep the patient alive.	**Case 84-6 (Question 3)**
NARCOLEPSY	
① Narcolepsy is an incurable neurologic disease characterized by sleep attacks and cataplexy. Stimulants modafinil or armodafinil help decrease sleep attacks and promote daytime alertness but do not help with cataplexy or nocturnal insomnia.	**Case 84-7 (Questions 1, 2)**
② Sodium oxybate is effective for cataplexy and improves nocturnal sleep, but it has high abuse potential and has been associated with psychiatric side effects.	**Case 84-7 (Questions 3, 4)**

OVERVIEW

Approximately one-third of the adult life is expended on sleep. The innate necessity of sleep is present in almost all mammals, though all the functions of sleep are not fully understood.[1,2] Naturally with human physiology devoted to sleep and the numerous factors that can disrupt this process, sleep disorders are remarkably common. Sleep deficiency, including insufficient sleep duration, irregular timing of sleep, poor sleep quality, and sleep or circadian rhythm disorders, is highly prevalent and threaten public safety.[3,4] Decades of scientific findings associate sleep deficiency with increased disease risk, including cardiovascular and metabolic disease, psychiatric illness, substance abuse, pregnancy complications, and impaired neurobehavioral and cognitive impairment.[4,5] At least 10% of the American population is reported to suffer from a sleep disorder that is clinically significant and of public health concern.[3] Major sleep disorders in the United States include insomnia ranging from 15% to 35%,[6,7] sleep apnea at 6% to 24%[8,9] periodic limb movements in sleep (PLMS, previously known as nocturnal myoclonus), and restless leg syndrome (RLS) ranging from 3% to 15%,[10,11] and narcolepsy at 0.025% to 0.05%.[12] Untreated sleep disorders, including chronic insomnia, sleep apnea, PLMS, and narcolepsy, are all associated with diminished mental and physical functioning and poor quality of life.[3,4,7]

Nightmares, nocturnal leg cramps, and snoring are more benign sleep disorders. Nightmares occur in 5% to 30% of children 3 to 6 years of age, and approximately

2% to 6% of adults have weekly nightmares.[13] Sleepwalking occurs in 1% to 2% of the population. Complex sleep behavior disorders, such as driving or eating while still half asleep, are uncommon to rare. These behaviors are more common in people taking hypnotics, and medication counseling should be provided for patients prescribed any sleep medication.[13,14]

CIRCADIAN RHYTHM AND SLEEP CYCLES

Sleep is a dynamic process with a cyclical recurrence and varying stages. The endogenous sleep–wake pattern of humans is based on the solar day–night cycle called the circadian rhythm. Circadian rhythm is controlled both by internal and external factors and sets the sleep–wake cycle at 24.2 hours. Sensory input (visual and acoustic) or other external factors modify the "internal clock" to a 24 hour day through working with the internal network and signaling brain centers to either wake or sleep. Thus, darkness is a visual cue that prepares the brain for sleep. Similarly, bright light serves to prepare the brain for wakefulness.[1,2]

Once sleep is initiated, it alternates between the two phases of rapid eye movement (REM) and nonrapid eye movement (NREM) sleep. These phases vary in length throughout the sleep cycles. During a normal night of sleep, a person generally has four to six cycles of sleep which last an average of 90 minutes (vary 70–120 minutes).[15] See Figure 84-1 for normal sleep cycles by age.

Polysomnography

Each sleep stage serves a physiologic function and can be monitored in sleep laboratories by polysomnography (PSG). PSG is the term used to describe three electrophysiologic measures: the electroencephalogram (EEG), the electromyogram, and the electrooculogram of each eye. It may also include an electrocardiogram, air thermistors, abdominal and thoracic strain belts, and oxygen saturation monitoring. The pattern of brain waves, muscle tone, and eye movements measured can be used to categorize the various sleep stages.[15,16]

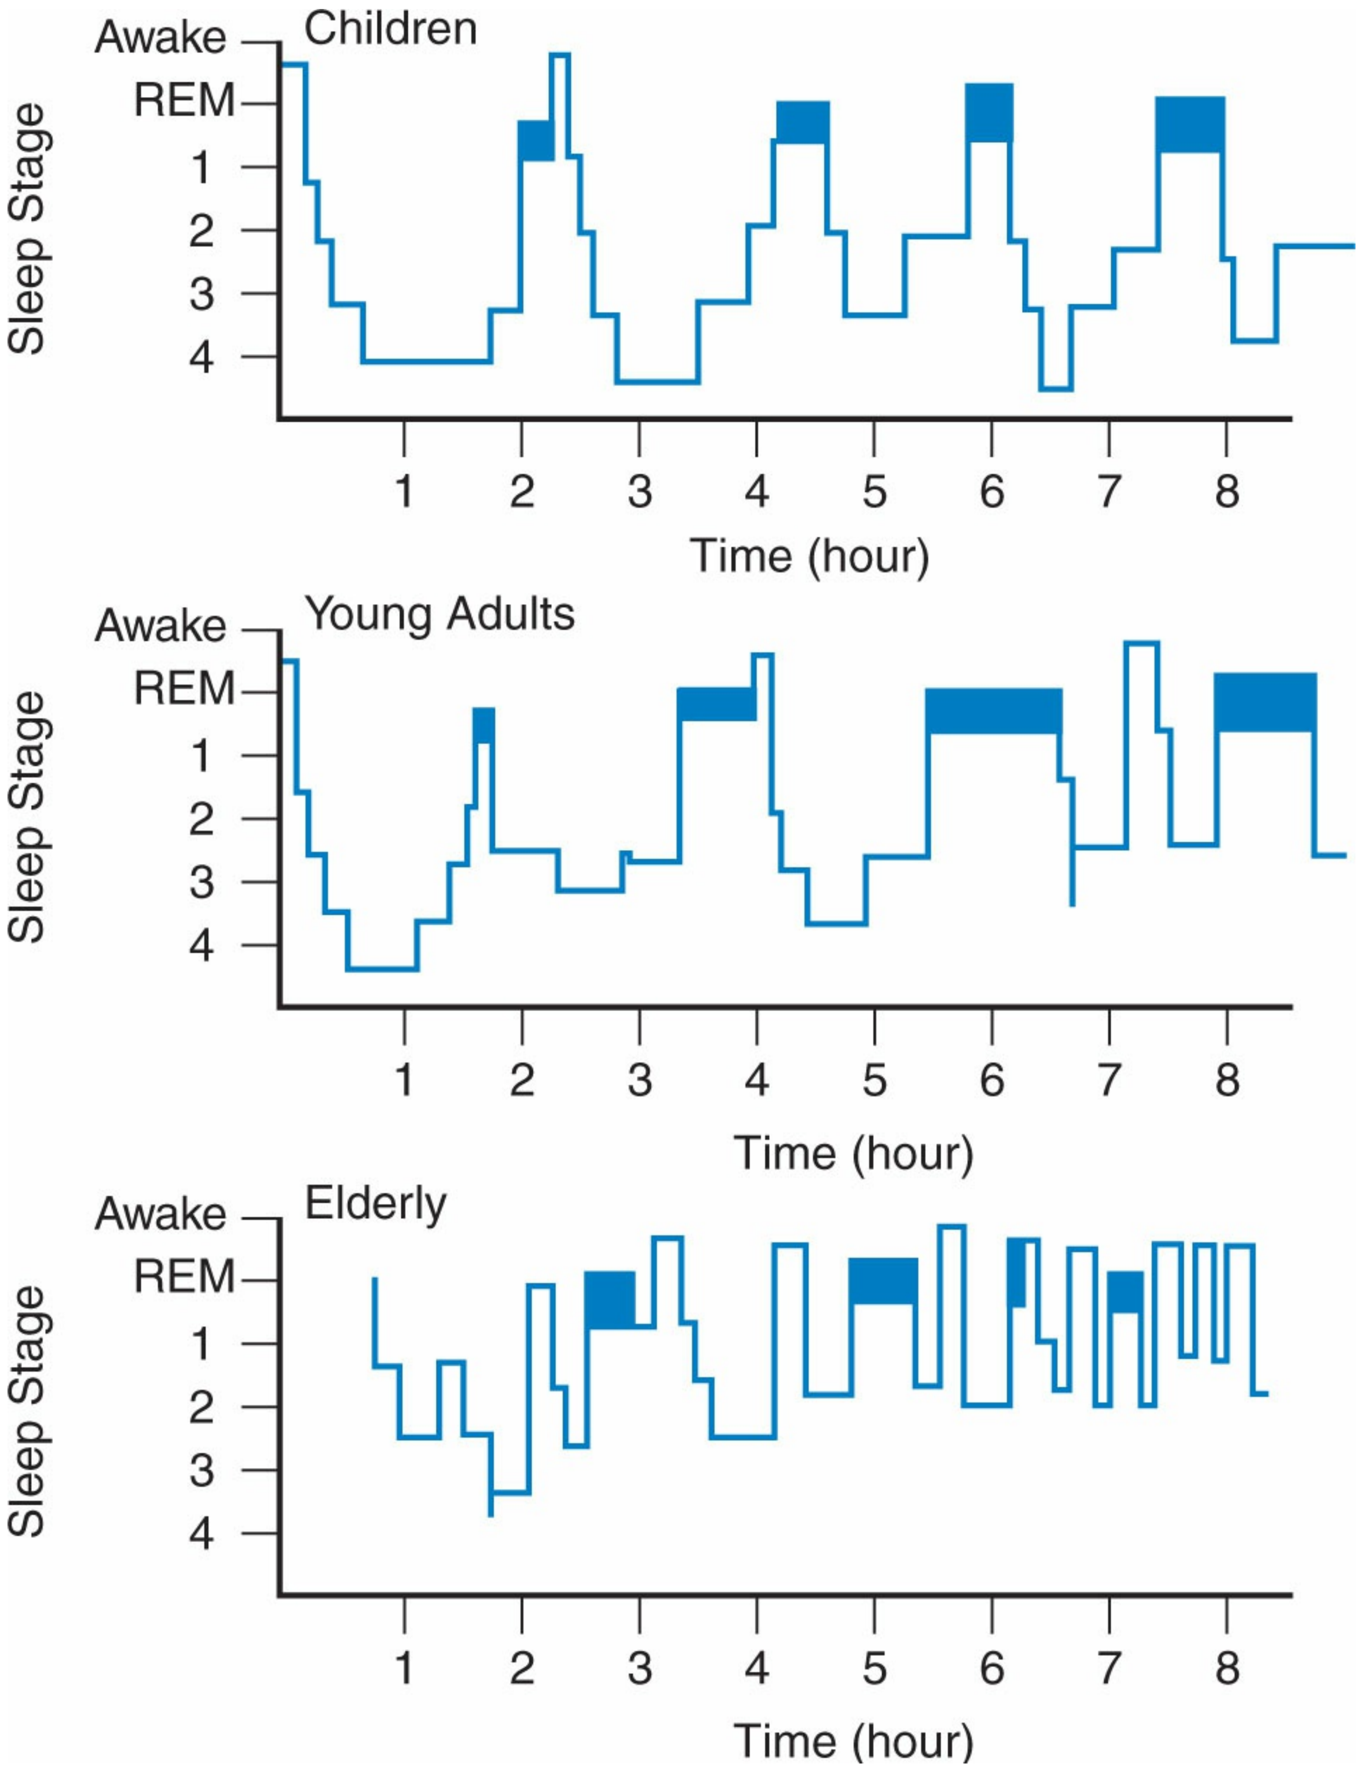

Figure 84-1 Normal sleep cycles.

Nonrapid Eye Movement Sleep

NREM sleep is divided into four stages, with different quantities of time and functions in each stage. Stage 1 is a transition between sleep and wakefulness known as relaxed wakefulness, which generally makes up approximately 2% to 5% of sleep. The function of stage 1 is to initiate sleep. Approximately 50% of total sleep time is spent in stage 2, which is rapid-wave (theta) or lighter sleep. Stage 2 provides rest for the muscles and brain through muscle atonia and low-voltage brain wave activity. Arousability from sleep is highest during stages 1 and 2. Stages 3 and 4 are slow-wave (delta) or deep sleep. Stage 3 occupies an average of 5% of sleep time, whereas stage 4 constitutes 10% to 15% of sleep time in young, healthy adults. In contrast to stages 1 and 2, it is difficult to awaken someone during stages 3 and 4, or delta sleep.[15] Delta sleep, also known as restorative sleep, is enhanced by serotonin, adenosine, cholecystokinin, and IL-1. The ability of IL-1 to promote slow-wave sleep supports a widely held theory linking deep sleep to the augmentation of immune function. Some hormones (e.g., somatostatin, growth hormone) are released mainly during slow-wave sleep. Deep sleep is most abundant in infants and children and tends to level off at approximately 4 hours a night during adolescence. At age 65, deep sleep accounts for only 10% of sleep, and at age 75, it is often nonexistent.[1,15–17]

Rapid Eye Movement Sleep

Whereas NREM sleep is necessary for rest and rejuvenation, the purpose of REM sleep remains a mystery. REM sleep is greatest in infants, accounting for about 50% of total sleep time. As aging occurs before 2 years and throughout adulthood, REM sleep is usually 20% to 25% of sleep. This percentage of total REM sleep

is maintained into healthy old age, but can decline markedly in the presence of organic brain dysfunctions of the elderly. REM sleep is also called paradoxical sleep because it has aspects of both deep sleep and light sleep. Body and brainstem functions appear to be in a deep sleep state as muscle and sympathetic tone drop dramatically. In contrast, neurochemical processes and higher cortical brain function appear active. Dreaming is associated closely with REM sleep, and when a person is awakened from REM, alertness returns relatively quickly.[15]

Numerous physiologic functions are altered during REM sleep. Breathing is irregular, consisting of sudden changes in respiratory amplitude and frequency corresponding to bursts of REM. Temperature control is lost and the body temperature typically lowers. REM sleep brings on variability in heart rate, blood pressure (BP), cerebral blood flow, and metabolism. Cardiac output and urine volume decrease. Blood may become thicker as a result of autonomic instability and temperature changes.[1,15–17]

REM duration varies throughout the night but increases each cycle. In the last half of the night, REM becomes notably longer and more intense when body temperature is at its lowest, around 5 AM. The human body clearly needs REM sleep, although the reason it occurs is unknown. When deprived of REM sleep, whether through poor sleep, drugs, or disease states, the brain and body try to catch up. REM rebound occurs and may result in vivid dreams or an overall less restful sleep.[15–18]

NEUROCHEMISTRY OF SLEEP–WAKE CYCLE

Wakefulness- and Sleep-Promoting Neurochemicals

A basic understanding of brain neurochemistry is essential in understanding sleep disorders and the clinical use of hypnotics. Hypnotics exert their effects by modulating brain neurotransmitters and neuropeptides (e.g., serotonin, norepinephrine, acetylcholine, histamine, adenosine, and γ-aminobutyric acid [GABA]). The neuronal systems in which neurotransmitters and neuropeptides act to control the sleep–wake cycle lie in the brainstem, hypothalamus, and basal forebrain, with connections in the thalamus and cortex. Noradrenergic, histaminergic, and acetylcholine-containing neurons promote wakefulness as they modulate cortical and subcortical neurons.[18] Excitatory amino acids, such as glutamate and stimulating neuropeptides (e.g., substance P, thyrotropin-releasing factor, corticotropin-releasing factor) also promote wakefulness.[18] Hypocretin 1 and 2, also known as orexin A and B, are neuropeptides that modulate the sleep–wake cycle. Hypocretin 1 and 2 are deficient in people with narcolepsy and primary hypersomnia.[15,18–20]

Wakefulness and sleep are antagonistic states competing for control of brain activity. Sleep takes over as the wakefulness-maintaining neuronal systems weaken and sleep-promoting neurons become active. Serotonin-containing neurons of the brainstem raphe dampen sensory input and inhibit motor activity, promoting the emergence of slow-wave sleep.[15,16,18] Opiate peptides (e.g., enkephalin, endorphin) and GABA, an inhibitory neurotransmitter, also promote sleep.[15,21]

Drug-Induced Effects on Neurochemicals

The neurochemistry of sleep also can be understood by considering the effect of hypnotic drugs on specific neurotransmitters. GABA is facilitated when a benzodiazepine compound attaches to the GABA–chloride ionophore complex and causes chloride channels to open and inhibit overexcited areas of the brain.[22,23] GABA-facilitating hypnotics, such as benzodiazepines, induce sleep and decrease arousals between stages, providing more continuous stage 2 sleep.[18,22,24] Benzodiazepines, however, also may decrease stage 4 slow-wave sleep and suppress REM, leading to REM sleep rebound on abrupt discontinuation.[15,22,24] Antihistamines that promote sleep do so by blocking histamine-containing neurons involved in maintaining wakefulness. The excitatory effects of caffeine and other methylxanthines are attributed to their antagonism of adenosine receptors. Adenosine is a sleep-promoting neurotransmitter or neuromodulator.[18,20]

Neurotransmitter alteration may or may not affect REM sleep. Drug-induced noradrenergic and serotonergic modulation usually decreases REM sleep. An increase in dopaminergic neurotransmission can increase wakefulness but has no direct effect on REM sleep. In contrast, increased cholinergic neurotransmission triggers REM sleep.[18] It is useful to think of the brain centers, neurochemicals, and neuropeptides involved as an interactive network regulating our sleep–wake cycle. Hence, drugs or disease states that alter neurotransmission can have significant impact on the sleep–wake cycle.

Diagnosis

The International Classification of Sleep Disorders, Third Edition (ICSD-3)[25] and the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5)[26] are the latest editions of guides used for classification and diagnosis of sleep disorders. Both ICSD-3 and DSM-5 categorize sleep disorders largely based on pathophysiology and presumed etiology rather than numbers of hours of sleep. See Table 84-1 for DSM-5 classifications of sleep disorders.

INSOMNIA

During the course of a year, approximately one-third (30%–36%) of the population will experience insomnia, and 10% to 15% will consider the problem severe due to daytime consequences.[25] Sleep research also shows that chronic insomnia can predict untreated illness or may contribute to injury and illness.[2,27–29] Children, adolescents, and adults with persistent insomnia are twice as likely to develop anxiety and 4 times as likely to develop depression when compared to people without insomnia.[27] Chronic insomnia is also more common in individuals with high blood pressure, breathing difficulties, gastrointestinal (GI) disorders, cancer, and chronic pain, among other conditions.[27–29] Insomnia and excessive daytime sleepiness (EDS) in the elderly are leading predictors of institutionalization.[30]

To meet the criteria for insomnia disorder according to ICSD-3 and DSM 5, the sleep disturbance must cause significant distress or impairment in important areas of functioning (i.e., social, occupational, educational, academic, behavioral) and occur at least three nights per week over a 3-month period despite adequate opportunity for sleep.[25,26] The insomnia disorder can be further classified based on duration as follows: episodic (1–3 months), persistent (>3 months), and recurrent (two or more episodes in 1 year). Insomnia with duration less than 1 month, previously referred to as transient insomnia, would be classified as “other specified insomnia disorder.”[25]

Patient Assessment

When first assessing a patient, it is important to determine whether the sleep problem is related to difficulty falling asleep, maintaining sleep, early morning awakening, nonrestorative–quality sleep, excessive daytime sleepiness, or a combination of these problems. Answers to the questions, “How long does it take you to fall asleep, and how many hours do you sleep?” should be compared with the patient’s normal sleep pattern to determine how it varies. Questions such as “How do you feel during the day: well rested, sleepy, or something else?” can help assess functional impairment. In addition, the patient’s sleep schedule, including bed time, sleep onset latency, number and length of nighttime awakenings, time to sleep reinitiation, and total wake and sleep time should be reviewed.[31]

Table 84-1

Classification of Sleep–Wake Disorders[26]

Insomnia disorder: too little or unrestful sleep; can have no identifiable underlying cause or be comorbid with a medical condition or another sleep or mental disorder
Hypersomnolence disorder: sleeping too much or experiencing drowsiness at times when individual should be alert
Narcolepsy/hypocretin deficiency: characterized by EDS, regardless of the time of day resulting in suddenly falling asleep; patients may also experience cataplexy, sleep paralysis, and hypnagogic hallucinations.
Breathing-related sleep disorders: most individuals with breathing problems that interfere with sleep experience fragmented sleep and complain of daytime drowsiness
Obstructive sleep apnea hypopnea
Central sleep apnea
Sleep-related hypoventilation
Circadian rhythm sleep–wake disorders
Sleep phase syndrome: falling asleep and waking earlier or later than desired
Irregular sleep–wake type: falling asleep and waking at irregular times
Non-24-hour sleep–wake type: falling asleep and waking progressively later than desired
Shift work type: sleep changes associated with work schedule
Non-REM sleep arousal disorders
Sleep terror type: individuals cry out in apparent fear during the first part of the sleep cycle but do not awaken; considered pathological only in adults
Sleep walking type: recurring sleepwalking, usually during the first part of the sleep cycle

Nightmare disorder: troubling dreams that awaken individuals or make them fearful of falling asleep

REM sleep behavior disorder: individuals may speak, thrash about, and/or awaken during REM sleep

Restless leg syndrome: individuals experience the need to move their legs during periods of inactivity, especially at night; can lead to fragmented sleep and daytime drowsiness

Substance/medication-induced sleep disorder: can result in insomnia or hypersomnolence

Other specified, or unspecified, sleep disorder: sleep–wake disorders that do not meet criteria for any of the above categories

EDS, Excessive daytime sleepiness; REM, Rapid eye movement.

The next step involves investigating the possible causes of the sleep disorder and any concomitant conditions. All coexisting medical, psychiatric, drug, environmental, and social causes must be considered and treated along with the sleep disorder. Impact of the sleep disturbance on daytime functioning should be assessed to evaluate the severity of the disorder. A sleep diary in which the patient records bed and wake times, estimated time to fall asleep, number and duration or awakenings, time and type of medication/substance ingestion, time and duration of any naps, and sleep quality can help to elucidate the type of sleep disorder.[31]

Table 84-2

Nonpharmacologic Treatments for Insomnia[32–34]

1. Cognitive-behavioral therapy: focus is on modifying behavioral and cognitive factors that lead to and foster sleep disturbances
   Cognitive: identify and stop thought patterns that interfere with sleep
   Behavioral: stimulus control, sleep restriction, relaxation, paradoxical intention.
   a. Stimulus control: train the brain to re-associate the bed and bedroom with sleep and re-establish a consistent sleep–wake schedule.
   b. Sleep restriction: create “sleep debt” by limiting amount of time in bed to only the total number of hours actually spent sleeping, then increasing time in bed as sleep efficiency improves.
   c. Relaxation therapy: target physiologic hyperarousal resulting from stress and tension (e.g., meditation, progressive tensing and relaxing of muscles, yoga, stretching).
   d. Paradoxical intention: encourage patient to engage in most feared behavior, “staying awake,” to reduce performance anxiety associated with falling asleep.
2. Sleep hygiene: not considered effective on its own; useful adjunctive treatment.
   Avoid caffeine, stimulants, heavy meals, and alcohol at bedtime; exercise early in the day before dinner to relieve stress and prime brain for sleep; turn the face of the clock away from view; establish a before-bedtime ritual; use the bedroom only for sleep and intimacy; make sure bedroom is dark, quiet, comfortable; avoid daytime napping.

Additionally to assessing patient symptoms and determining the cause of insomnia, it is important to discuss patient expectations. Not all patients need the same amount of sleep, and too much sleep can be as problematic as too little sleep.[26]

Nonpharmacologic Treatment

The first-line treatment for chronic insomnia should be psychological and behavioral therapies. Cognitive-behavioral therapies (CBTs) are effective, long-lasting interventions for insomnia and considered the standard of care.[32,33] They may be more effective than pharmacotherapy for sleep onset latency and sleep efficiency.[34,35] The sleep benefits of these interventions are not immediate and can take several weeks to successfully implement. Results vary depending on the individual and their severity and chronicity of insomnia.[34] Table 84-2 lists established cognitive and behavioral interventions with brief descriptions in addition to important sleep hygiene strategies to include in patient counseling.[32]

Pharmacologic Treatment

Pharmacotherapy is indicated for a variety of reasons, including when nondrug interventions fail or cannot be implemented, sleep

---

disturbances produce significant distress or impairment and immediate symptom relief is required, patient preference is for drug therapy, or if insomnia is comorbid with another medical, sleep, or psychiatric disorder.[32] Patients often do not seek treatment for insomnia from their healthcare provider when pharmacologic treatment is warranted. Instead, alcohol or OTC sleep aids are used with unfavorable results that can worsen insomnia or next-day functioning.[35–37]

The ideal hypnotic has a rapid onset of effect (within 20 minutes, the natural time to fall asleep), helps the patient sleep throughout the night, does not cause daytime impairment, and carries no abuse potential. Currently, there are no ideal hypnotics. Hypnotics that are benzodiazepine receptor agonists come closest to the ideal.[35,38] Available agents vary in onset, duration, and potential for daytime impairment, mostly because of their individual pharmacokinetic profiles (Table 84-3).[39] The selection of an appropriate hypnotic should consider the type of insomnia to be treated and the physiologic characteristics of the patient. For example, if someone cannot fall asleep but has no trouble staying asleep and wants to prevent next-day carryover effects, a rapid-acting hypnotic with short half-life and no active metabolites is desirable.[35,38,39] Age, sex, socioeconomic status, and comorbidities also influence the hypnotic prescribed.[37–40]

INSOMNIA IN A NORMALLY HEALTHY PATIENT

CASE 84-1

QUESTION 1: P.B., a 36-year-old man, is requesting a medication for treatment of his sleep disorder. He returned to Boston, Massachusetts, from a month long business trip to California 2 days ago and is now having difficulty falling asleep. When he initially arrived in California 4 weeks ago, he went to sleep immediately at 7 PM and awoke at 3 AM. His sleep pattern adjusted during his 4-week visit in California, but upon returning to Boston, it now takes him 2 to 3 hours to fall asleep. He has difficulty awakening in the morning and, as a result, sleeps past 9 AM. He needs to be able to wake-up by 6 AM and be alert during the day in his job as an accountant.

What information provided by P.B. is important in the assessment of his sleep disorder? What additional information should be obtained from P.B. to assist in the assessment of his sleep disturbance?

P.B. describes a circadian rhythm sleep–wake disorder, specifically sleep phase syndrome related to a time-zone shift (previously referred to as "jet lag"). His major complaint is difficulty falling asleep and awakening later than desired, because he reports no trouble staying asleep or awakening too early. It is important for P.B. not to be sedated during the day so that he can fulfill his job obligations. Additional information needed from P.B. includes the duration of insomnia, methods already tried to relieve insomnia and their efficacy, concomitant medications, coexisting medical conditions or psychiatric disorders, alcohol use, caffeine use, and current life stressor. P.B. should be advised that assessing all of the aforementioned information is necessary in treating his sleep problem.

CASE 84-1, QUESTION 2: In response to your additional questions, you learn that P.B. has no medical problems and takes no prescription medications. He has been taking pseudoephedrine at night for nasal congestion since returning from California. He denies drinking alcoholic beverages and coffee but admits to recently increasing his cola intake from infrequent consumption of 1 to 2 cans between lunch and bedtime to try to stay awake. He denies a long history of sleep disorder, but adds, "I have not been able to sleep as well since traveling; I don't know why." What factors could be contributing to P.B.'s complaints?

Several factors are contributing to P.B.'s type of sleep disorder. His circadian rhythm has been disrupted because of travel, but he also takes a stimulating decongestant (i.e., pseudoephedrine) and drinks a caffeine-containing beverages (i.e., average can of cola has about 35 mg of caffeine; PB consumes 35–70 mg/day). In addition, he sleeps in new surroundings that may require time for adjustment. All these factors can contribute to difficulty in falling asleep. Circadian rhythm sleep disorder results from a mismatch between the sleep–wake schedule required by a person's environment and the circadian sleep–wake pattern.

NONPRESCRIPTION SLEEP AIDS

CASE 84-1, QUESTION 3: P.B. would like to purchase a nonprescription sleep medication. What would you recommend?

An individual risk-versus-benefit assessment is essential before recommending any medication, including OTC products. Although OTC products (i.e., antihistamines, melatonin, valerian, and other herbals) are commonly advertised as sleep aids, data supporting the use of these products are limited. Antihistamines can cause drowsiness and may help patients fall asleep. The ability to cause sedation does not necessarily lead to hypnotic efficacy. Some patients do not feel well rested the next day after taking an antihistamine, but instead feel slow, lethargic, and not mentally sharp. This "hangover effect" can be significant and may be related to the lipid solubility and central histaminic (H_1) and muscarinic blocking effects of the antihistamine.[35,41] Antihistamines with low lipid solubility (e.g., cetirizine, loratadine) do not cross the blood–brain barrier readily and do not cause sedation. Although diphenhydramine is the most common antihistamine found in nonprescription sleep medications, some preparations contain the antihistamines doxylamine or hydroxyzine.

CASE 84-1, QUESTION 4: What additional counseling is needed for P.B.?

Tolerance can develop to the sedative effects of antihistamines after 3 to 7 days of continued use.[35,37–38,41] Because of a high incidence of daytime sedation and risk of cognitive psychomotor impairment,[33] antihistamines are a poor choice for P.B., an accountant who must stay alert and functional throughout the day. Any attempt to manage P.B.'s sleep disorder should start with nonpharmacologic interventions before initiating any drug therapy.

TIME-ZONE SHIFT: NONPHARMACOLOGIC TREATMENT VERSUS TRIAZOLAM OR NONBENZODIAZEPINE RECEPTOR AGONISTS

CASE 84-1, QUESTION 5: P.B. asks whether he can try triazolam for the treatment of his sleep disturbances. What would you recommend?

P.B. should be informed about the likely causes of his sleep disturbances (i.e., time-zone shift, caffeine-containing beverages, pseudoephedrine, new surroundings). He also should understand that it may take 1 to 3 weeks for his system to readjust after traveling.[42] The importance of nonpharmacologic interventions, particularly those that pertain to reestablishing a desired sleep–wake cycle and sleep hygiene education, to improve sleep (Table 84-2) should be emphasized. In addition, an hour of bright light in the morning can serve as an environmental stimulus, normalizing the circadian rhythm.[42] If P.B.'s sleep disturbances persist despite adhering to cognitive-behavioral interventions, a prescription hypnotic may be necessary.

Table 84-3

Sedative-Hypnotic Agents FDA-Approved for Treatment of Insomnia[36–38,61]

	Dose (mg)					
Generic[a] (Brand	Healthy	Elderly Hepatic	Onset	Half-Life	Duration of	Insomnia

Name)	Adults	Impairment	(minutes)	(hours)	Action[b]	Indication
Benzodiazepines						
Estazolam (generics)	1–2	0.5–1	60–120	10–24	Intermediate	Sleep onset and sleep maintenance[f]
Flurazepam (generics)	15–30	NR	60–120	>100[c]	Long	Sleep onset and sleep maintenance[f]
Quazepam (Doral, generics)	7.5–15	NR	30–60	47–100[c]	Long	Sleep onset and Sleep maintenance[f]
Temazepam (Restoril, generics)	7.5–30	7.5	60–120	3.5–18.4	Intermediate	Sleep onset and sleep maintenance[f]
Triazolam (Halcion, generics)	0.125–0.25	0.125	15–30	1.5–5.5	Short	Sleep onset[f]
Nonbenzodiazepine Receptor Agonists						
Zaleplon (Sonata)	10–20	5–10	30	1	Short	Sleep onset[f]
Zolpidem						
Oral tablet (Ambien)	5–10[d]	5	30	1.4–4.5	Short	Sleep onset[f]
ER oral tablet (Ambien CR)	6.25–12.5[d]	6.25	30	1.62–4.05	Intermediate	Sleep onset and sleep maintenance[g]
Sublingual tablet[e] (Intermezzo)	1.75–3.5[d]	1.75	20–38	1.4–3.6	Short	Middle-of-the-night-awakening[h]
Sublingual tablet[e] (Edluar)	5–10[d]	5	30	1.57–6.73	Intermediate	Sleep onset[f]
Mucous membrane spray (Zolpimist)[i]	5–10[d]	5	10	2.7–3	Short	Sleep onset[f]
Eszopiclone (Lunesta)	1–3 (start with 1 in all patients)	1–2	30	6	Intermediate	Sleep onset and sleep maintenance[g]
Melatonin Agonist						
Ramelteon (Rozerem)	8	8	30	1–5[c]	Short	Sleep onset[g,j]
Orexin Receptor Antagonists						
Suvorexant (Belsomra)	10–20 (5–10 with moderate CYP3A4 inhibitor)	Elderly—Not specified Severe hepatic	30	12	Intermediate	Sleep onset and maintenance[g]

		dysfunction = NR				
Antidepressants						
Doxepin (Silenor)	6	3	30	15.3 (31[c])	Intermediate	Sleep maintenance[g,j]

[a] Dispense with a product-specific Medication Guide.

[b] Time the patient feels the effects after a single dose; usually approximates half-life with multiple doses; individual variability exists; and tolerance may develop with continued use, lessening the duration; short = 1 to 5 hours; intermediate = 5 to 12 hours; long = >12 hours.

[c] Half-life includes the parent compound and its active metabolites.

[d] In women start with the lower dose.

[e] To be dissolved under the tongue and not swallowed whole.

[f] FDA approved for short-term (7–10 consecutive days) treatment of insomnia.

[g] Not limited to short-term use.

[h] Take only if 4 hours remaining before planned wake time.

[i] To be sprayed over the tongue immediately before bedtime

[j] Not a controlled substance.

FDA, U.S. Food and Drug Administration; NR, Not recommended; ER, Extended-release.

Short-acting hypnotics (Table 84-3)[35,38,41,43] like triazolam are effective to induce and regulate sleep if the stay will be relatively short (<5 days) and if critical activities must be accomplished during the first 48 hours after arrival at the destination.[42] Triazolam, indicated for difficulties with sleep latency, has a rapid onset of sedative-hypnotic activity (within 15–30 minutes). Triazolam also has a short half-life of approximately 1.5 hours that does not contribute to next-day impairment at recommended doses (0.125–0.25 mg for healthy adults, 0.125 mg for elderly). Women may be more susceptible to the adverse effects of hypnotics than men, possibly due to greater oral bioavailability.[35,41] P.B. could ask his physician to prescribe triazolam 0.125 mg, as needed. Disadvantages of benzodiazepines, and triazolam in particular, include the impairment in new learning or anterograde amnesia and the potential for complex sleep behaviors (e.g., eating, sleeping, driving, or other activities while being asleep). These effects can interfere with daytime functioning and result in the inability to remember new information learned on the trip. P.B. should be cautioned regarding tolerance to the hypnosedative effects and physiologic dependence that can occur with long-term use of a benzodiazepine and the potential for rebound insomnia with abrupt discontinuation.[35,37,41] Of the benzodiazepine receptor–active hypnotics, triazolam is most commonly associated with rebound insomnia (i.e., daytime nervousness, jitteriness, and insomnia worse

---

than before) if abruptly stopped after more than 7 to 10 days of continuous use and withdrawal problems, likely related to its high binding affinity at different gamma-aminobutyric acid $(GABA)_A$ receptor subtypes.[43–45] The pharmacologic properties of benzodiazepines, including sedation, anterograde amnesia, antianxiety and anticonvulsant activity, muscle relaxation, and ethanol potentiation, occur as a result of interaction with various $GABA_A$ receptor subunits. The sedative effects of benzodiazepines are primarily mediated via activity at the α_1-subunit of the $GABA_A$ receptor.[45] Nonbenzodiazepine hypnotics (NBRA; also known as Z-hypnotics) such as zaleplon, zolpidem, and eszopiclone have fewer reports of rebound insomnia and anterograde amnesia at recommended doses due to selectivity for the α_1-receptor subunit and also lack significant anxiolytic and muscle relaxant effects compared with triazolam.[43] Also, triazolam's short half-life and rapid decrease in blood levels create the potential for withdrawal symptoms including anxiety and insomnia. Triazolam is highly effective in inducing sleep when used on an as-needed basis. Long-acting hypnotics, such as flurazepam, may prevent the traveler from awakening in the morning and should be avoided.

MELATONIN

CASE 84-1, QUESTION 6: P.B. would like to try melatonin for improved sleep but wonders whether it is safe and effective. What information is available on the safety and efficacy of melatonin for circadian rhythm or other types of sleep disorders?

Melatonin is a naturally occurring hormone secreted by the pineal gland, located in the center of the brain. The pineal gland is connected to the retina via a nerve pathway that runs through the suprachiasmatic nucleus of the hypothalamus, the body's circadian clock. The pineal gland produces melatonin (a by-product of serotonin metabolism) only during the nocturnal phase of the circadian cycle and only in the presence of relative darkness.[41,46]

Studies in adults show that melatonin has at least mild sleep-promoting properties when administered before the period of natural increase in endogenous melatonin (~10 PM to midnight). It causes significantly more sleepiness when taken at 8 PM compared with 11:30 PM, theoretically because the brain's receptors are already saturated with melatonin late at night.[41,46] Doses between 0.5 and 5 mg taken close to the target bedtime in the new time zone can decrease sleep disturbances. A systematic review of 10 clinical trials showed melatonin was more effective for travel eastward crossing multiple time zones.[46] Melatonin 0.5 to 10 mg has been found effective for entraining the circadian rhythms in blind people, alleviating insomnia in developmentally disabled, handicapped, or autistic spectrum children and adults, and treating short-term, initial insomnia in children with attention deficit hyperactivity disorder (ADHD).[41,46,47] The safety and effectiveness of melatonin for long-term use or other sleep disorders has not been established. Consumers selecting melatonin products over the counter should be advised the purity of melatonin is not regulated by the FDA. Although doses of 0.5 to 5 mg melatonin are well tolerated, side effects include sleepiness, headache, and nausea.[41,46,47] Melatonin use has been associated with reports of depression, liver disease and vasoconstrictive, immunologic, and contraceptive effects.[41,46]

RAMELTEON

CASE 84-1, QUESTION 7: P.B.'s doctor gave him a prescription for ramelteon 8 mg at bedtime. How does ramelteon compare with melatonin?

Ramelteon is a highly selective melatonin agonist at melatonin 1 and 2 receptors (MT1, MT2). MT1 regulates sleepiness and MT2 adjusts circadian rhythms and regulates phase shifts from day to night.[48,49] Ramelteon is approved by the FDA for insomnia characterized by difficulty falling asleep. Clinical studies in primary insomnia show it decreases the time to fall asleep by 10 to 19 minutes, and it increases total sleep time by 8 to 22 minutes.[48–50] One controlled trial showed it was superior to placebo in decreasing time to fall asleep during a 6-month period, although ramelteon's onset was 15 minutes faster than placebo after week one but only 9 minutes faster at 6 months.[49] Its half-life ranges from 1 to 2.6 hours. The half-life of its active metabolite, M II, is 2 to 5 hours. Ramelteon undergoes hepatic metabolism by cytochrome P-450 isoenzyme CYP1A2. Increases in serum concentration occur even with mild liver disease, so caution is recommended for patients who have at least moderate liver disease. Fluvoxamine is a strong inhibitor of CYP1A2 and given with ramelteon dramatically increases its serum concentration. Coadministration with fluvoxamine or any potent CYP1A2 inhibitors should be avoided. The most common adverse events observed with ramelteon include headache (7%), dizziness (5%), somnolence (5%), fatigue (4%), and nausea (3%).[49,50]

In clinical trials, no evidence of cognitive impairment, rebound insomnia, withdrawal effects, or abuse potential was demonstrated even at doses up to 20 times the usual treatment dose.[51] These results were markedly different than the abuse potential and side effects of triazolam at treatment doses and doses up to 3 times higher than usual.[48,49,52] Of note, no study has directly compared ramelteon and another hypnotic for insomnia management.[52] Ramelteon is a reasonable option for patients with initial insomnia with no abuse potential and little to no risk of next-day impairment.

NONBENZODIAZEPINE RECEPTOR AGONISTS (ZOLPIDEM, ZALEPLON, AND ESZOPICLONE)

CASE 84-1, QUESTION 8: It has been a month since his return and P.B. continues to have difficulty falling asleep. What alternative medications (aside from triazolam and ramelteon) offer rapid onset, have low risk of daytime sedation, and can be administered safely for weeks to months if necessary?

Considering their rapid onset of action, NBRA medications (zaleplon, zolpidem, and eszopiclone) are all potential alternatives for P.B. They have varying degrees of selectivity for the α_1-subunit on the $GABA_A$ receptor. This selectivity imparts hypnotic efficacy with no significant anxiolytic, muscle relaxant, or anticonvulsant effects. Consequently, NBRAs have a lower risk of abuse, withdrawal, and tolerance compared with older nonselective benzodiazepines such as triazolam and temazepam. These attributes make NBRAs more desirable for the treatment of chronic insomnia. Both zolpidem controlled-release and eszopiclone are FDA-approved for chronic insomnia and are effective for up to 3 to 6 months of therapy.[38] Zolpidem has been studied up to 12 months and was not associated with rebound insomnia or withdrawal symptoms.[53]

Additionally, eszopiclone was studied for 12 months of nightly administration and found to be well tolerated with no tolerance observed.[54] Another potential advantage of NBRAs α_1-subunit selectivity is little to no change in sleep architecture or sleep stages. Temazepam and flurazepam increase the percentage of stage 2 sleep but can suppress REM and stage 3 and 4 deep restorative sleep. In contrast, NBRAs do not interfere with these sleep stages and have lower rates of uncomfortable REM rebound (vivid dreams, increased autonomic instability) on discontinuation.[38,44]

The NBRAs differ with respect to pharmacokinetics and adverse events. Zolpidem, the first NBRA, was marketed in the United States in 1991. It is absorbed rapidly, reaches peak serum levels in 1.5 hours, and is eliminated rapidly with an average half-life of approximately 2.5 hours.[42] For faster sleep onset, zolpidem should be taken on an empty stomach for faster absorption. A food-effect study demonstrated that administration of a zolpidem 10 mg tablet 20 minutes after a meal resulted in a decrease in AUC and C_{max} of 15% and 25%, respectively, and an increase in the T_{max} from 1.4 to 2.2 hours.[55] Zolpidem is metabolized by the oxidative cytochrome P-450 isoenzyme CYP3A4; therefore, drug interactions should be considered when zolpidem is coadministered with CYP3A4 inhibitors such as diltiazem or fluoxetine. Zolpidem has no active metabolites, and it has a low risk of residual daytime sedation in recommended doses.[38,43] Zolpidem controlled-release (CR) has no clear advantage over zolpidem, except that it may provide a slightly longer duration of sleep. Zolpidem CR is a bilayered tablet that has a first layer that dissolves quickly to induce sleep and a second layer that releases zolpidem more gradually to improve sleep maintenance. Serum concentrations peak in 2 hours compared with 1.5 hours for immediate-release zolpidem, with an associated longer latency to effect.[39] Of note, zolpidem has been approved as oral spray to help with sleep onset. Due to buccal absorption, it has a rapid-onset of action of 10 minutes.[56] In 2013, the FDA approved a new label change and dosing for zolpidem products to recommend avoiding driving the day after using zolpidem controlled-release. Also, gender metabolism differences exist where women metabolize zolpidem slower than men, resulting in blood levels nearly two-fold higher. As a result, in women or the elderly, the recommended starting dose is 5 mg zolpidem immediate-release or 6.25 mg zolpidem extended-release.[57] For P.B., though the usual adult dose in males for zolpidem immediate-release is 10 mg at bedtime, women, elderly, or patients such as P.B, who express concern that a medicine may be too strong, should begin with 5 mg at bedtime.

Zaleplon offers a shorter elimination half-life (approximately 1 hour) and duration of effect than zolpidem (see Table 84-3). It is least likely of all hypnotic agents to cause residual daytime sedation and has the least effect on memory and psychomotor performance. An assessment of psychomotor performance, arousal, memory, and cognitive functioning with zaleplon revealed no cognitive impairment.[38,43] The most common adverse effects with zaleplon include dizziness, headache, and somnolence.[58] In dose escalation studies using up to 60 mg, symptoms appear at approximately 30 minutes after dosing, peak at 1 to 2 hours, and are no longer evident after 4 hours. It can be taken in the middle of the night as long as the individual has 4 hours left in bed. Zaleplon is metabolized primarily via aldehyde oxidase, CYP3A4 is a secondary route of metabolism, and there are no active metabolites; it has less potential for drug or food interactions compared with zolpidem or eszopiclone.[41]

Eszopiclone maintains efficacy with no evidence of tolerance after 6 months of continuous use, resulting in FDA approval for long-term use.[59–62] Hypnotic efficacy has been demonstrated for up to 6 months in younger patients taking 2 to 3 mg nightly, and in elderly patients taking 1 to 2 mg nightly, although only the higher range of doses significantly improved sleep maintenance. As with zolpidem and zaleplon, eszopiclone has a rapid onset of effect, but differs in that it has a longer duration of effect (Table 84-3). Time to maximal concentration (T_{max}) is delayed up to 1 hour when eszopiclone is administered after a high-fat meal, potentially delaying the onset of sleep.[59,60]

Eszopiclone has less receptor selectivity than either zaleplon or zolpidem, potentially resulting in some anxiolytic, amnestic, and anticonvulsant activity.[61] Among the three Z-hypnotic drugs, eszopiclone has a dose-related unpleasant bitter taste noted by 16% to 34% of patients.[59,60] Headache and dizziness were reported more commonly with eszopiclone than placebo, and at higher doses, next-day confusion and memory impairment were reported in up to 3% of patients.[38,60] Eszopiclone is primarily metabolized by CYP3A4, so drugs that induce or inhibit this isoenzyme can have an impact on metabolism and a clinical effect.[60]

P.B. needs a medication that will hasten sleep onset, but does not need continued drug effect later in the night. Both zolpidem and zaleplon are useful alternatives for

P.B. because of their efficacy for his sleep onset difficulty. However, zaleplon may be preferred due to quick onset and short half-life to mitigate the risk of next-day hangover. Among the NBRAs, eszopiclone has the longest half-life and the greatest risk for next-day impairment.

CASE 84-1, QUESTION 9: Zolpidem 5 mg is prescribed because of its rapid onset, low cost, and lower risk for next-day impairment. P.B. expresses concern about possible adverse effects owing to its labeling as a Schedule IV controlled substance and the FDA warning of complex sleep behaviors such as night eating and night driving. How should P.B.'s concerns be addressed?

Patient counseling is most effective when it is interactive with both patient and practitioner actively listening to each other while exchanging information. It is best to begin by emphasizing the benefits of zaleplon to improve his sleep and daytime functioning. Next, P.B. should be reassured that zaleplon is generally well tolerated and he will be prescribed the lowest dose to minimize the likelihood of adverse effects. Counseling should include a discussion of common and potentially serious adverse effects along with management strategies. Common possible adverse effects include headache (30%), abdominal pain (6%), asthenia (5%), somnolence (5%), and dizziness (7%).[38,58] Anaphylactoid reactions and nightmares have been reported in postmarketing studies. Additionally, P.B. should be encouraged to report both effectiveness and all adverse effects to his clinician. Alcohol should not be consumed together with zaleplon or any NBRA because it can cause excessive side effects and interfere with P.B.'s sleep.

To address P.B.'s concern regarding complex sleep behaviors, a reasonable response would be "rarely, individuals taking sleeping medication have been reported to be making phone calls, eating, having sex, or driving while half asleep. The risk for these potentially dangerous effects increases if consumers take a higher than the recommended dose, or drink alcohol or mix hypnotics with other sedating medications."[14] Another rare allergic reaction is facial swelling (angioedema). All manufacturers of hypnotic medication are required to include this information in their package inserts.[14]

Although the abuse potential of NBRAs is less than benzodiazepines, they are problematic in active substance abuse disorders. NBRAs are Schedule IV controlled substances with more potential for abuse than ramelteon or sedating antidepressants, like trazodone.[48] Tolerance and withdrawal associated with NBRAs is unlikely but reported with abrupt discontinuation and patients should be counseled of this possibility, particularly at high doses.

CASE 84-1, QUESTION 10: P.B. asks about a new sleep medication, suvorexant, and whether he could use this to help him sleep. What information can you provide P.B. regarding the safety and efficacy of suvorexant for insomnia?

Suvorexant is an orexin receptor antagonist FDA-approved in 2014 for treatment of insomnia characterized by difficulty falling asleep and/or maintaining sleep. The orexin signaling pathway promotes wakefulness and arousal; antagonism of orexin receptors can promote sleep. Studies show that suvorexant can decrease latency to onset of sleep and wake after sleep onset without disrupting the sleep architecture. The initial recommended daily dose is 10 mg within 30 minutes of bedtime and with at least 7 hours of sleep time available. Suvorexant should be taken on an empty stomach as time to sleep onset may be delayed by 1.5 hours if taken with or soon after a meal. If needed, the dose can be increased in 5 mg increments to the maximum recommended daily dose of 20 mg at bedtime. Suvorexant is a CYP3A substrate and a dose reduction of 5 mg daily is recommended when administered concurrently with a moderate CYP3A inhibitor; concurrent administration with a strong CYP3A inhibitor is not recommended.[63] No rebound insomnia or withdrawal symptoms have been observed following abrupt discontinuation.[64] When compared to zolpidem, suvorexant is associated with less abuse potential and like benzodiazepine receptor agonist hypnotics is a Schedule IV medication.[63] The most commonly reported adverse effect in clinical trials evaluating suvorexant was daytime somnolence. Complex sleep behaviors, a dose-dependent increase in suicidal ideation, sleep paralysis, hallucinations, and cataplexy-like symptoms have been reported with suvorexant. Suvorexant is contraindicated in patients with narcolepsy. Studies comparing suvorexant to other hypnotic agents, such as the Z-hypnotics, are lacking. The role of suvorexant in the treatment of sleep disorders has yet to be established.

INSOMNIA IN A MEDICALLY ILL PATIENT

Insomnia and Effect on Sleep Stages

CASE 84-2

QUESTION 1: A.T., a 42-year-old woman with a 5-year history of hypothyroidism and a 2-year history of hypertension and chronic lower back pain, was just transferred from the intensive care unit (ICU) into a medical unit. Her cardiac status is considered “stable” 2 days after a myocardial infarction (MI). She is 5 feet 9 inches tall and weighs 72 kg. She is receiving aspirin 81 mg (enteric-coated), levothyroxine 112 mcg, and felodipine 10 mg all taken by mouth 1 hour before breakfast every day. Her main complaint is insomnia, including difficulty falling asleep, difficulty maintaining sleep, and early morning awakenings. A.T. reports insomnia for 6 weeks before admission, which worsened during the hospitalization. What type of insomnia does A.T. have, and how might the insomnia affect her health?

A.T.’s insomnia is considered chronic because she experienced it for 6 weeks before hospital admission. It is severe because it involves difficulty falling asleep, maintaining sleep, and early morning awakening. Careful monitoring and effective treatment of A.T.’s sleep disturbance is crucial; studies show disrupted sleep can increase the risk of another adverse cardiac event owing to worsening autonomic instability and poor perfusion to the myocardium.[65]

Because normal sleep moves through all the stages of NREM and REM in a continuous cycle, a patient deprived of continuous sleep may not receive sufficient time in each sleep stage. When stage 2 is diminished, muscles have insufficient opportunity to rest and rejuvenate. If NREM stages 3 and 4 are eliminated, immune function and the healing process can be disrupted. If REM sleep is deprived or excessive, neurotransmitter function may be altered and physiologic homeostatic processes can be disrupted.[15,16,28]

Drug or Disease Etiologies

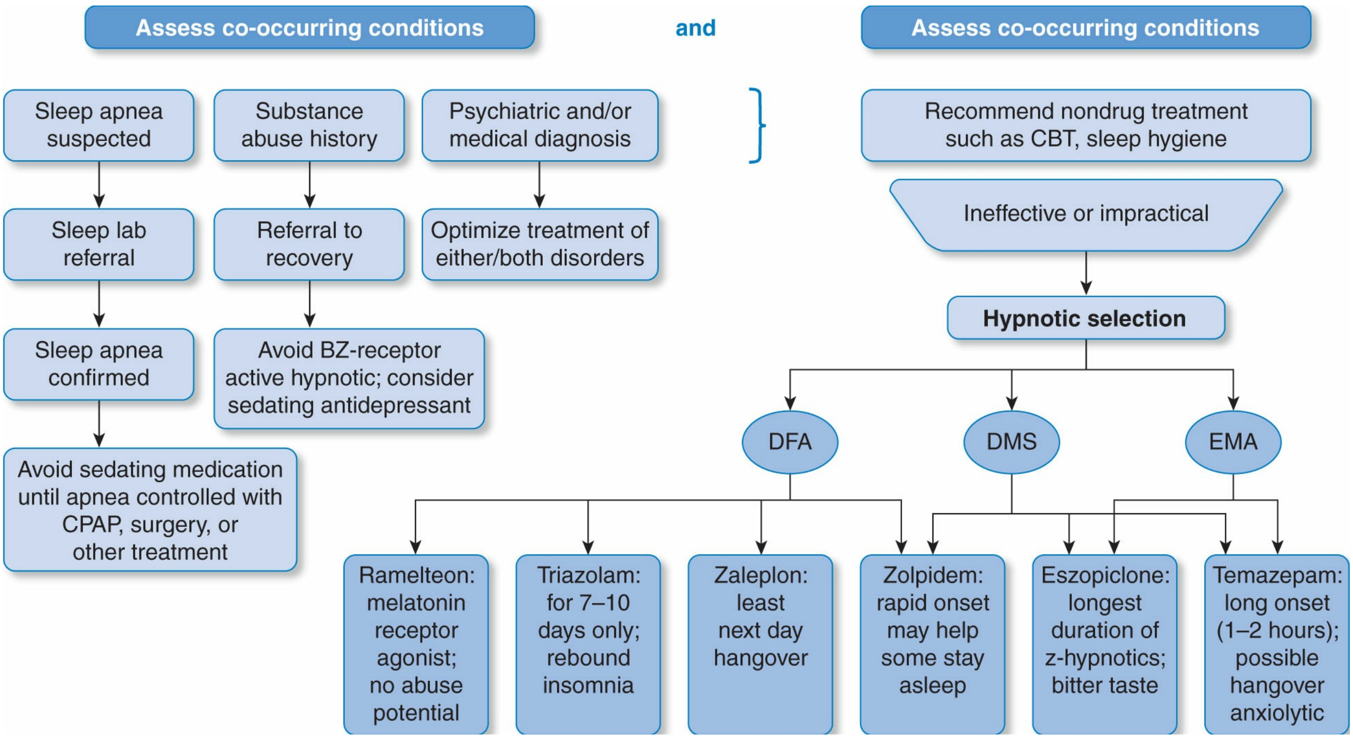
CASE 84-2, QUESTION 2: What individual drug or disease state factors should be assessed in A.T. before developing a treatment plan?

The Insomnia Treatment Algorithm in Figure 84-2 is useful in systematically addressing A.T.'s sleep complaint. It calls for thoroughly evaluating all concomitant conditions and the type of insomnia in each patient. Numerous medical disorders and primary sleep disorders are associated with difficulty falling asleep and maintaining sleep (Tables 84-4 and 84-5).[5,28,65] First, A.T. should be assessed for sleep apnea because untreated sleep apnea is a known etiology of cardiac disease and hypnotics can be dangerous in untreated sleep apnea (see Case 84-8, in the Sleep Apnea section). Second, A.T.'s pain management should be assessed for optimal efficacy. Acute post-MI pain adds to A.T.'s chronic lower back pain. Of patients with lower back pain, 50% experience chronic poor sleep patterns.[28,65] Third, A.T. was just transferred out of the ICU. Sleep deprivation in an ICU is common and is attributed to the continuous lighting, noise, and constant interventions. Sleep deprivation may prolong or worsen a disease process through diminished natural killer cell activity and decreased stages 3 and 4 of NREM sleep (when healing occurs).[41,66,67] Medications also may be contributing to A.T.'s insomnia (Table 84-4). Levothyroxine can overstimulate the CNS if given in excessive doses. A.T.'s thyroid status should be re-evaluated to ensure appropriateness of the thyroid dose, especially considering her post-MI status.[68] Calcium-channel blockers have been associated with occasional sleep disturbances; therefore, felodipine should be evaluated as a potential contributing factor.[68]

Another clue to a possible cause of A.T.'s sleep problem is her description of early morning awakening, which could be related to hospital activity during these hours or to the presence of a major depressive disorder. A.T. requires psychiatric evaluation to rule out depression, which occurs in about one-third of patients after an MI.[69] In general, patients with chronic illnesses are at increased risk of experiencing major depression, which typically presents with insomnia or hypersomnia. Interestingly, medical outcome studies of other chronic illnesses (cardiovascular, pulmonary, renal, neurologic disease) show a high prevalence of sleep disturbance even in those not suffering from depression.[28,65] Chronic insomnia related to multiple causes can be resistant to treatment; however, treatment of underlying causes increases the likelihood of insomnia resolution.

Comparing Available Hypnotics

CASE 84-2, QUESTION 3: A.T.'s pain is now under control, her levothyroxine dose is appropriate, and felodipine-induced sleep disturbance, sleep-disordered breathing, RLS, and PLMS have all been ruled out. A psychiatric evaluation finds that A.T. does not have major depression, but she is anxious about "life after a heart attack." She meets criteria for primary insomnia and adjustment disorder with anxiety. She continues to have trouble falling asleep and staying asleep. She will be discharged in 2 days. The psychiatric consultation suggests an adjunctive medication with anxiolytic properties that may also help with sleep. Which hypnotic is best for A.T., considering her individual clinical characteristics?



Assess co-occurring conditions
and
Assess co-occurring conditions
Sleep apnea suspected
Substance abuse history
Psychiatric and/or medical diagnosis
Recommend nondrug treatment such as CBT, sleep hygiene
Sleep lab referral
Referral to recovery
Optimize treatment of either/both disorders
Ineffective or impractical
Hypnotic selection
Sleep apnea confirmed
Avoid BZ-receptor active hypnotic; consider sedating antidepressant
DFA
DMS
EMA
Avoid sedating medication until apnea controlled with CPAP, surgery, or other treatment
Ramelteon: melatonin receptor agonist; no abuse potential
Triazolam: for 7–10 days only; rebound insomnia
Zaleplon: least next day hangover
Zolpidem: rapid onset may help some stay asleep
Eszopiclone: longest duration of z-hypnotics; bitter taste
Temazepam: long onset (1–2 hours); possible hangover anxiolytic

Figure 84-2 Algorithm for treatment of insomnia. DFA, difficulty falling asleep; DMS, difficulty maintaining sleep; EMA, early morning awakening.

Table 84-4

Potential Causes and Contributing Factors for Each Chronic Sleep Complaint[5,28,65]

Difficulty Falling Asleep (DFA)
Learned or conditioned activation (primary insomnia): restless legs syndrome (RLS)

Medications: methylphenidate, modafinil, fluoxetine, bupropion, steroid, β-blocker
Substances: caffeine, guarana, alcohol
Psychiatric disorders: schizophrenia, depression, anxiety disorder, bipolar disorder
Medical disorder: chronic pain, neuropathy, gastrointestinal disorder, cardiopulmonary disorders (particularly if in recumbent position)
Difficulty Maintaining Sleep (DMA)
Excessive time in bed
Psychiatric disorder: major depression, anxiety or bipolar disorder, substance abuse
Sleep-disordered breathing: sleep apnea, acute respiratory distress syndrome
Cardiac disease: atrial fibrillation, heart failure, angina
Neurologic disorder: dementia, Parkinson disease, multiple sclerosis
Early Morning Awakening (EMA)
Major depression
Advanced sleep phase syndrome: learned or conditioned activation (primary insomnia)
Forced to get up because of family or work obligations
Excessive Daytime Sleepiness
Medications: clonidine, antihistamines, antipsychotic, antidepressant, benzodiazepine, chloral hydrate, opioid, anticonvulsant, α_1-adrenergic blockers
Obstructive sleep apnea, central sleep apnea, narcolepsy
Chronic sleep deprivation

The ideal hypnotic for A.T. should act quickly and continue working throughout the night to provide her with uninterrupted sleep. A hypnotic that is not metabolized in the liver would have a lower potential for drug interactions and lessen the opportunity for systemic accumulation. If daytime drug concentrations are needed to calm anxiety, however, a hypnotic with slowly eliminated active metabolites may be desirable. The comparable doses of the hypnotic medications are listed in Table 84-3. When considering available hypnotic medications, differences in pharmacodynamic and pharmacokinetic properties should be considered (Table 84-3). Onset of effect is related to lipophilicity, receptor binding affinity, and T_{max}.[39,41]

Benzodiazepine Dependence and Tolerance

CASE 84-2, QUESTION 4: In further discussion with A.T., who prefers to try cognitive-behavioral interventions for anxiety reduction and sleep induction, temazepam 15 mg at bedtime is prescribed on an as-needed basis. A.T. will be monitored regularly as an outpatient for efficacy and tolerability. As A.T. is preparing to leave the hospital, her daughter expresses concerns about the potential for physical dependence on temazepam and the risk of A.T. becoming an addict. How would you respond to her concerns?

A benzodiazepine hypnotic that is nonselective is preferable in A.T. because of the need for anxiolytic properties in addition to hypnotic efficacy. NBRAs are not effective anxiolytic agents. The pharmacodynamic and pharmacokinetic properties of triazolam have already been presented. Its rapid onset is an advantage for A.T.;

however, the duration of action would not be sufficient to help A.T. stay asleep. In addition, it should not be used for longer than 7 to 10 days because of the greater potential for adverse effects with prolonged use and the possibility of significant rebound insomnia on withdrawal.[41] A.T. may require a hypnotic for more than 7 to 10 days, which is the maximal duration for triazolam use.

Table 84-5

Potential Causes of Chronic Sleep Disorders[5,28,65,68]

Psychiatric Disorders	
Anxiety disorders	Depressive disorders
Bipolar disorder	Psychotic disorders
Personality disorders	Somatoform disorders
Organic mental disorders	Substance abuse
Medical and Neurologic Disorders	
Angina pectoris	Dementia
Bronchitis	Peptic ulcer disease
Chronic fatigue	Hyperthyroidism and hypothyroidism
Cystic fibrosis	Asthma
Huntington disease	COPD
Parkinson disease	Epilepsy
Hypertension	Gastroesophageal reflux
Arthritis	Renal insufficiency
Cardiac disease	Connective tissue disease
Chronic pain	
Cancer	
Sleep Disorders	
RLS	Sleep apnea (obstructive or central)
PLMS (nocturnal myoclonus)	Primary snoring
Circadian rhythm sleep disorder (jet lag, shift work, delayed sleep phase)	Narcolepsy
Drugs Associated With Sleep Disturbance	
Insomnia	Hypersomnia
Alcohol	Alcohol
Bupropion	Benzodiazepines
Fluoxetine	Antihypertensives
Sertraline	Clonidine
MAO inhibitors	α-Adrenergic blockers
TCA	ACE inhibitors

Thyroid supplements	β-Blockers
Calcium-channel blockers	Anticonvulsants
Decongestants	Analgesics
Appetite suppressants	Chloral hydrate
Theophylline	Antipsychotics
Corticosteroids	Antihistamines
Dopamine agonists	Opioids

ACE, angiotensin-converting enzyme; COPD, chronic obstructive pulmonary disease; MAO, monoamine oxidase; PLMS, periodic limb movements during sleep; RLS, restless legs syndrome; TCA, tricyclic antidepressants.

Flurazepam induces sleep within 15 to 45 minutes during chronic dosing. On the first night of use, however, flurazepam does not induce sleep as well as triazolam. It has intermediate fat solubility but depends on the plasma concentrations of its metabolite, N-desalkylflurazepam, for most of its activity.[41] N-desalkylflurazepam concentrations take approximately 24 hours to accumulate and induce sleep. Studies show flurazepam maintains efficacy in sleep induction for at least 30 days; N-desalkylflurazepam has weak receptor binding affinity and a long half-life, resulting in gradual elimination and little chance for rebound insomnia.[41] N-desalkylflurazepam can accumulate during chronic dosing and affect daytime cognition in some patients or compete for hepatic metabolism, resulting in altered levels of other hepatically metabolized medications.[41,68] A.T. has difficulty moving around during the day because of her chronic lower back pain, and oversedation from accumulation may impair her daytime functioning. Flurazepam is infrequently used because of the risk of next-day impairment; it is useful to explore other options. Similarly, quazepam having an extended half-life and potential for drug accumulation would not be an optimal agent for A.T.

Temazepam takes 1 to 2 hours to induce sleep. It has moderate fat solubility, similar to N-desalkylflurazepam, but it has a longer dissolution time. Temazepam takes 1.5 to 2 hours to reach peak plasma concentrations. Temazepam's longer dissolution time is caused by its large drug particle size in a gelatin capsule. A potential advantage for using temazepam in A.T.'s case is its lack of hepatic oxidative metabolism and intermediate duration of action of 8 to 12 hours. It does not interfere with the metabolism of other hepatically metabolized drugs and it does not accumulate, minimizing the potential for daytime impairment relative to flurazepam.[41,70] The long onset of action may be of concern, although A.T. could take the drug an hour before bedtime to optimize timing for sleep.

For A.T., the most appropriate choice is temazepam. Of the five approved benzodiazepine agents approved for insomnia (see Table 84-3), temazepam's advantages are intermediate duration of activity that would keep her asleep throughout the night, anxiolytic benefit, and low risk of daytime impairment owing to no known active metabolites.[41,70]

Fear of dependence and addiction to medications is a concern among the general public. Television station "medical experts" and popular magazine "health sections," while providing information, may increase the potential for confusion, erroneous impressions, and misinformation. For healthcare practitioners, it becomes even more crucial to provide sound drug information in common, easy-to-understand terms.

An example of the practitioner's response may be, "I'm glad you have expressed a concern; it gives us a chance to discuss temazepam therapy before your mother leaves the hospital." Temazepam has been prescribed for a medical reason, to improve your mother's sleep and to aid in her healing process. One therapeutic benefit of temazepam is an 8-hour duration of effect. Your mother will be able to sleep throughout the night so that she is well rested during the day. It also may decrease her anxiety over not sleeping, and that puts less stress on her heart.

"The possible side effects of temazepam include sedation, unsteadiness, and dizziness. She should let her doctor know if she experiences any adverse effects. Right now, it is unclear how long your mother will be taking temazepam. Duration of therapy needs to be assessed on an ongoing basis. If your mother takes temazepam every night for more than 4 weeks, two things could happen: (a) she may develop a tolerance and it may not help her sleep anymore, or (b) her system may develop a dependence in which she may have worse insomnia if she does not take it. The primary concern is not addiction but the possible dependence. This means your mother should not change her dose or stop on her own. Any changes in dose or stopping must be done slowly and with her doctor's involvement. These two scenarios do not always occur and are not likely because your mother will be taking it on an as-needed basis. If one or the other does happen, some other intervention may be tried to help with her sleep, or the temazepam dose can be gradually decreased to prevent

---

withdrawal problems. It is important to advise your mother to avoid alcohol, and report any decrease in effectiveness or any adverse effects to her healthcare practitioner."

Patients taking benzodiazepines for longer than 1 year tend to be older, medically ill, and chronically dysphoric and have panic disorder or chronic insomnia. Most chronic use appears to be medically appropriate and does not lead to dose escalation or abuse. Among chronic dysphoric patients, the indications are less clear, and dose escalation is noted sometimes without notable therapeutic benefit. Benzodiazepine hypnotics rarely are taken alone for pleasure and generally are not likely to be abused. Among substance abusers, however, they frequently are taken as part of a polysubstance abuse pattern by alcoholics and narcotic, methadone, and cocaine users. In these groups, abuse is highly prevalent. Benzodiazepines are used to augment euphoria (narcotics and methadone users), to decrease anxiety and withdrawal symptoms (alcoholics), and to ease the "crash" from stimulant-induced euphoria (cocaine users).[71,72]

Physiologic dependence on benzodiazepines, resulting in a withdrawal and abstinence syndrome, develops usually after 2 to 4 months of daily use of the longer half-life benzodiazepines. Shorter half-life benzodiazepine use can result in physiologic dependence earlier (days to weeks) and may be associated with more withdrawal problems.[41,44] See Table 84-3 for a comparison of pharmacokinetic properties of hypnotics.

INSOMNIA AND PSYCHIATRIC DISORDERS

Stepwise Approach to Selecting a Hypnotic

CASE 84-3

QUESTION 1: M.B., a 33-year-old woman, is hospitalized after a suicide attempt in which she tried to overdose on sertraline, ibuprofen, and diphenhydramine. Before the suicide attempt, M. B. had been sober for 3 years. She is diagnosed with major depression and alcohol substance use disorder. After completing an interview with M.B., you learn she stopped taking fluoxetine 5 months ago due to insomnia. She reports doing well until 3 months ago where depression symptoms worsened during her divorce. Two weeks before admission, her outpatient primary-care doctor prescribed sertraline for depression and omeprazole for acid reflux. She went on a drinking binge 5 days ago that ended with the suicide attempt. Her target symptoms include early morning awakening, trouble falling asleep, 15-pound weight loss, apathy, social withdrawal, depressed mood, hopelessness, and anhedonia. Medications continued in the hospital include sertraline 100 mg daily and omeprazole 20 mg daily. M.B. currently reports feeling restless and sleeping only 3 to 4 hours a night. Use Tables 84-3 and Figure 84-2 to compare the clinically significant differences between available hypnotics and to demonstrate how such information can be used to develop a patient-specific treatment plan. What is the best approach to solving M.B.'s sleep problem?

The Insomnia Treatment Algorithm outlined in Figure 84-2 serves as a useful guide for the assessment and management of M.B.'s sleep complaint. Concomitant conditions and the type of insomnia (difficulty falling asleep, difficulty maintaining sleep, early morning awakening) are assessed simultaneously. Possible causes or contributing factors are identified and treated. The type of insomnia can aid in treatment selection. Cognitive-behavioral interventions can be implemented if M.B. is willing and able to participate.

Factors to consider in the drug selection process include substance abuse history, the need for rapid onset and duration of effect. For example, agents with long-acting metabolites (e.g., flurazepam) may accumulate or cause daytime hangover. If the hypnotic has no hepatic metabolism, it will not be subject to drug interactions with other agents that are hepatically metabolized. Also, if insomnia is chronic and resistant to hypnotic treatment, or if a low abuse potential agent is desired (e.g., for a person with an existing substance use disorder like M.B.), trazodone or another sedating antidepressant may be selected.

Sleep Disturbance of Depression

CASE 84-3, QUESTION 2: What type of insomnia does M.B. have, and how is it different from other types of insomnia?

M.B. has trouble falling asleep and early morning awakening, and sleep time has decreased to 3 or 4 hours a night. She is diagnosed with major depression, and sleep difficulty is part of the disorder. Generally, initial insomnia and early morning awakening are associated with depression, although difficulty maintaining sleep and next-day fatigue are common as well. M.B. is most bothered by trouble falling asleep, early morning awakening, and next-day fatigue. Up to 65% of outpatients with major depression report one or more symptoms of sleep disturbance, whereas 90% of inpatients with depression like M.B. report insomnia.[73]

The insomnia of depression is likely related to a dysregulation of neurotransmitters, such as serotonin, norepinephrine, and dopamine, in addition to dysregulation of the hypothalamic–pituitary axis. All are involved in regulating mood and the sleep–wake cycle.[16,66] Neurotransmitter activity is modified by the effects of antidepressants on REM sleep. Most pro-serotonergic antidepressants suppress REM, causing increased REM latency and decreased total REM time.[73,74] Indeed, REM sleep deprivation can elevate mood.[73,75] Depressed patients deliberately deprived of REM sleep have had a reduction in depressive symptoms. In addition to effects on REM, antidepressants redistribute slow-wave sleep to more physiologically natural patterns, with increased intensity in the first half of the night.[75] Sedating antidepressants with serotonin 2 (5-HT$_2$) antagonist properties, such as trazodone and mirtazapine, alleviate insomnia and improve sleep architecture.[73]

CASE 84-3, QUESTION 3: M.B. and the treatment team ask you what factors other than depression (i.e., medications, alcohol) may contribute to M.B.'s insomnia. How can her sleep problem be solved?

Treatment

The treatment for M.B.'s insomnia should begin with patient education. She should be informed that more than 90% of depressed patients have some sleep disturbance, either too little or too much, and her sleep should improve as depressive symptoms improve (in 2–8 weeks). Counseling on cognitive-behavioral interventions to improve sleep may be appropriate when M.B.'s depression begins to clear and she is more motivated to improve her sleep hygiene. In the meantime, the potential contribution of sertraline causing restlessness or insomnia should be assessed by confirming the drug is dosed in the early morning to minimize this effect.[70] A sedating antidepressant such as mirtazapine may be preferred unless M.B.'s history includes a positive response with sertraline that would justify ongoing treatment. M.B. also was using alcohol before admission. Alcohol disrupts sleep and can increase arousal when its sedative effects wear off, leading to more fragmented sleep.[37] All patients should be counseled to have their last alcoholic drink at least 3 hours before sleep. M.B. should avoid

---

alcohol altogether given her history of abuse. Drug and alcohol withdrawal and the lingering "abstinence syndromes" often are associated with insomnia, although sometimes hypersomnia is the predominant symptom.[37,76]

HYPNOTICS

CASE 84-3, QUESTION 4: What is the evidence for trazodone's use in managing insomnia? What other antidepressants are used in the treatment of insomnia? Discuss the advantages and disadvantages of using sedating antidepressants for the treatment of insomnia in M.B.

Prescribing a hypnotic short-term or a sedating antidepressant is recommended for depressed patients with insomnia because a good night's sleep can improve treatment adherence and daytime functioning until antidepressant effects become apparent.[65,66] All antidepressants, including selective serotonin reuptake inhibitors (SSRIs), such as sertraline, can improve sleep as the depression lifts; however, most antidepressants like SSRIs, serotonin norepinephrine reuptake inhibitors (e.g., venlafaxine, desvenlafaxine, duloxetine), bupropion, and monoamine oxidase inhibitors can all cause insomnia as well.[68,73] Analysis of residual symptoms in partially treated depressed patients taking SSRIs shows continuing insomnia is present in 44%, requiring additional interventions such as trazodone or mirtazapine.

Hypnotics that act at benzodiazepine receptors are not recommended for M.B. due to her drug use history and recent alcohol abuse. Older nonselective benzodiazepines like temazepam can have a euphoric effect, are cross-tolerant with alcohol, and are likely to be abused by patients with alcohol and substance abuse problems.[41] Abuse, dependence, and withdrawal reactions have been reported with newer $GABA_A$ receptor α_1-subunit selective NBRAs (zolpidem, zaleplon, eszopiclone); therefore, neither class of drugs is appropriate for M.B.[38,58]

If the clinician determines that sertraline treatment is preferred, then trazodone may be added to alleviate insomnia.[77] The addition of trazodone to fluoxetine, bupropion, or monoamine oxidase inhibitors decreased time to sleep and increased duration of sleep but caused intolerable sedation in a few patients who received fluoxetine. Tolerance did not develop to the sedative effects of trazodone in short-term studies (<6 weeks) used adjunctively for depression; however, decreased benefit with time has been reported.[77] The 5-HT_2 antagonist properties of trazodone at low dosages, in addition to its antagonism at histamine-1 and α_1 adrenergic receptors, provide the rationale for its efficacy as a sedating agent.[78]

Trazodone is not thought to be a highly effective antidepressant medication because most people cannot tolerate an effective dose (300–600 mg/day). Because of its sedating properties, low-dose trazodone (50–200 mg/day at bedtime) has become a commonly prescribed adjunctive medication to induce sleep while awaiting the onset of another primary antidepressant's effect.[77] Trazodone has a half-life of approximately 6.4 hours in younger adults and 11.6 hours in the elderly. It undergoes hepatic metabolism via CYP2D6 and CYP3A4; thus, inhibitors of these isoenzymes can increase blood levels and worsen side effects. The most common side effects of trazodone include drowsiness (29.1%), dizziness (21.9%), and dry mouth (17.7%). Cardiac arrhythmias are possible at doses greater than 200 mg/day, as is priapism, a painful prolonged erection that occurs in 1 of 1,000 to 10,000 men. Although priapism is considered rare, it can lead to impotence if untreated; therefore, men should be counseled about priapism at any dose of trazodone.[77]

In the only placebo-controlled trial of trazodone conducted in primary insomnia, investigators compared the hypnotic efficacy of trazodone and zolpidem with placebo in 306 adults (21–65 years of age). Subjects were randomly assigned to receive trazodone 50 mg, zolpidem 10 mg, or placebo nightly for 2 weeks. Sleep parameters were assessed using a subjective sleep questionnaire, which patients completed each morning and at weekly office visits. Trazodone was found to be as effective as zolpidem for the first week of treatment, but during the second week, only zolpidem was more effective than placebo.[77] Tricyclic antidepressants (TCAs; e.g., amitriptyline, doxepin) were used to treat primary insomnia for years based on case reports describing efficacy in doses of 10 to 75 mg/night.[41,73] TCAs, however, increase the risk of cardiovascular problems and anticholinergic side effects in a dose-related manner (see Chapter 86 Depression).

Ultra-low-dose doxepin 3 and 6 mg tablets are now available (Silenor) for the treatment of insomnia characterized by difficulties with sleep maintenance. Doxepin is not a controlled substance, so it may be of value in patients with a history of substance abuse. Four clinical trials conducted in slightly more than 1,000 patients demonstrated ultra-low-dose doxepin's efficacy and safety in both younger adults and the elderly.[79] Doxepin demonstrated improved sleep efficiency during the final third of the night and in the seventh and eighth hours of sleep. Doxepin was well tolerated, with residual sedation and anticholinergic effects no different than placebo. There were no significant effects on next-day alertness, memory, or psychomotor function. Hypnotic efficacy with doxepin was demonstrated for up to 3 months. The primary disadvantage of this brand formulation is its cost. It remains to be seen whether these low-dose studies will prompt increased use of generic doxepin 10 mg, and whether any advantages can be demonstrated in using the branded formulation.

For M.B, a TCA raises additional safety concerns. M.B. has a history of substance abuse and prior suicide attempts. Both are risk factors for future suicide attempts. TCAs are more toxic in overdose when compared with trazodone, and there are multiple reports of TCA plasma levels increasing to toxic levels when administered in combination with CYP450 2D6 inhibitors (see Chapter 86, Depression).

Switching to mirtazapine as an antidepressant that offers more sedation is a reasonable consideration for M.B. If M.B. has a partial but significant response to sertraline at maximal tolerated doses and good tolerability except for insomnia at 4 weeks, mirtazapine can be added to facilitate remission. Mirtazapine has 5-HT_2 antagonist and antihistamine effects, which impart sedation, and it is safer than TCAs in overdose.[73] Mirtazapine is not associated with priapism, but it can cause weight gain.

INSOMNIA IN THE ELDERLY

CASE 84-4

QUESTION 1: S.D., a 77-year-old man, is seen for his initial geriatrics primary-care clinic visit. Vital signs include temperature, 98.8°F; heart rate, 58 beats/minute; respiratory rate, 18 breaths/minute; BP, 166/69 mm Hg; height, 5 feet 3 inches; and weight, 109 pounds. He was referred from an emergency department (ED) visit 4 days earlier with complaints of palpitations and anxiety. Before his ED visit, his medications included atenolol 50 mg daily, lorazepam 1 mg at bedtime, and saw palmetto 320 mg daily. At his ED visit, he stated he had taken lorazepam for sleep for more than 1 year, but did not take it the prior 2 nights and started feeling palpitations and anxiety. His electrocardiogram showed normal sinus rhythm at 67 beats/minute, and S.D.'s head computed tomography scan was negative for any hemorrhage. S.D. was told not to restart the lorazepam, but instead to take diphenhydramine 50 mg at bedtime. He took only one dose, felt "terrible" and fatigued for the next 2 days. On further questioning, he states that he falls asleep without difficulty, usually

---

awakens 2 to 3 times each night to urinate, and often has difficulty falling back to sleep. In the past, lorazepam was helpful with his sleep difficulty. What considerations are important for the assessment and treatment of insomnia in an elderly patient such as S.D.?

Treatment of insomnia in the elderly represents a therapeutic dilemma. Evidence supports an increased need to treat insomnia in the elderly to reduce its potentially serious complications, yet many drug treatment options have potential for harm that may outweigh their benefit. In a large epidemiological study of sleep complaints in 9,282 individuals 65 years and older conducted by the National Institute on Aging, 57% of subjects indicated at least one sleep complaint occurring most of the time, 19% had difficulty falling asleep, 30% complained of awakening at night, and 19% complained of awakening too early.[80] Despite such high frequency of sleep complaints, these complaints are primarily thought to be more a marker of poor physical and mental health rather than caused by aging itself.[80,81]

Historically, it was accepted that age-related sleep changes begin in early adulthood and progress steadily across the adult lifespan.[82] However, in a meta-analysis of 65 studies of quantitative sleep parameters across the lifespan of individuals from ages 5 to 102 without sleep complaint, most changes in sleep were found to occur by age 60.[73] Changes in sleep latency are small and subtle, with an overall increase between 20 and 80 years of less than 10 minutes. Increases in percentages of stage 1 and 2 sleep, as well as decreases in total sleep time, percentage of slow-wave and REM sleep, and REM latency, were significant with aging up to age 60, but only minimal changes were seen after age 60. Only sleep efficiency was found to continue to significantly decrease after age 60. Therefore, identifying factors underlying sleep complaints in the elderly is critical and can lead to appropriate diagnosis and treatment. Elderly patients need not be resigned merely to getting the sleep that they do because they are "getting older."[82]

CASE 84-4, QUESTION 2: What are the more common underlying causes of sleep complaints in the elderly?

Common precipitants of acute insomnia in the elderly include acute medical illnesses, hospitalization, changes in the sleeping environment, medications, and acute or recurring psychological stressors. Chronic or long-term insomnia may be associated with a variety of underlying medical, behavioral, and environmental conditions, as well as a variety of medications.[83] Identification of treatable underlying causes should be the first step in management of insomnia, based on a medical and medication history, physical and mental status examination, and laboratory investigations including thyroid function, serum chemistry panel, and cardiopulmonary studies if indicated.[83,84] Special attention should be directed to chronic pain from any cause, pulmonary disease, chronic renal disease, neurologic disorders, and polyuria from urinary, prostate, or endocrine disorders. Medical conditions with a strong association with insomnia include heart disease, hypertension, diabetes, stomach ulcers, arthritis, migraine, asthma COPD neurological problems, menstrual problems, depression, and bipolar disorder.[85,86] Primary sleep disorders are RLS, sleep apnea, and circadian rhythm disorders.[65,81,86] The potential contribution of medications to the sleep complaint needs to be evaluated, and changes in medication or timing of administration should be considered. Many drugs with CNS effects can alter patterns of sleep and wakefulness, both during their use and their withdrawal.[36,80,86] Both prescribed and OTC medications must be evaluated. The more common drugs of concern include stimulants (caffeine, nicotine, and amphetamines), alcohol, activating antidepressants (e.g., SNRIs and bupropion), pseudoephedrine, bronchodilators, β-blockers, calcium-channel blockers, corticosteroids, and dopamine agonists. Evening administration of drugs like diuretics may also contribute to nighttime awakenings and sleep complaints.

Psychological Versus Drug Treatments for Insomnia

CASE 84-4, QUESTION 3: Which nondrug therapy treatment options might be appropriate for S.D.?

CBT is an effective and safe alternative to drug therapy for insomnia and has also been shown to be an effective augmenting treatment with drug therapy.[34,35] CBT limitations include that it is little known, not widely available, and more time-consuming than drug therapy. Both pharmacologic and nonpharmacologic approaches are effective for the short-term management of insomnia in late life, and current evidence suggests that sleep improvements are better sustained over time with behavioral treatment.[34] A comparative meta-analysis of 21 studies of pharmacotherapy and behavior therapy for persistent insomnia in adults found that both treatments similarly produced moderate to large improvements in number of awakenings, wake time after sleep onset, total sleep time, and sleep quality.[87] Behavior therapy, however, resulted in a greater reduction of sleep latency than pharmacotherapy. CBT was compared with pharmacotherapy (zolpidem) and its combination in 63 young and middle-aged adults with chronic sleep onset insomnia.[34] There was a significant difference in percent change in improved sleep onset latency (CBT 52%, combination therapies 52%, zolpidem 14%, placebo 17%). No significant differences were found among the groups in total sleep time. The authors concluded that CBT, alone or in combination with pharmacotherapy, was more effective than pharmacotherapy alone or placebo for the treatment of sleep onset insomnia. Avoidance of medications with their associated costs, adverse effects, and drug interactions is the primary advantage of CBT. Disadvantages of CBT include possible longer time to effective treatment, higher initial cost, and relative paucity of trained providers in many areas.[88]

CASE 84-4, QUESTION 4: What are the concerns about the use of lorazepam or another benzodiazepine in S.D.?

Specific concerns need to be addressed about the risks most associated with benzodiazepines in the elderly regarding dependence, risk of falls, cognitive dulling, and memory loss. Concern about dependence and the nontherapeutic use of benzodiazepines has been an important factor in limiting the long-term treatment of insomnia with hypnotic drugs.[89] In insomnia patients specifically, the risks of dependence and recreational use of benzodiazepines are relatively low. Dose escalation appears to occur only when treatment is ineffective, or when the patient has a history of substance abuse or anxiety. Although still controversial, the risk of dependence and abuse associated with the newer nonbenzodiazepine drugs may be lower than that associated with benzodiazepine hypnotic drugs. An even greater concern with benzodiazepine use in the elderly is the risk of falls and subsequent hip fractures. Using 42 months of Medicaid healthcare claims data in New Jersey for more than 125,000 individuals older than 65 years, the association of hip fractures and benzodiazepine use was evaluated.[90] Compared with not being exposed to a benzodiazepine, exposure to any benzodiazepine was associated with a 54% higher rate of hip fracture, and after adjusting for potential confounding variables, benzodiazepine use was associated with a 24% higher rate of hip fracture. Use of short half-life benzodiazepines was found to be no safer than use of long half-life benzodiazepines, and the risk of hip fracture was highest during the first 2 weeks after starting a benzodiazepine. These findings support the usual recommendation that the elderly should be given lower doses than their younger adult counterparts, but they challenge the suggestion that only long half-life drugs should be avoided in the elderly owing to clearance concerns. Elderly patients should also be monitored closely to prevent cognitive decline caused by benzodiazepines and avoid use when possible.[91]

CASE 84-4, QUESTION 5: What are the concerns about the use of diphenhydramine in S.D.?

Sedating antihistamines are not recommended for treating insomnia in the elderly, as there is no evidence of sustained benefit and they pose significant risk of anticholinergic effects, notably cognitive impairment, dry mouth, urinary retention, and constipation.[36,88,92] Duration of sedative effect efficacy from antihistamines is also problematic with tolerance to sedative effects developing quickly (3–7 days).[93,94]

S.D.'s primary sleep complaint is related to his nocturia. He is self-treating his urinary symptoms with saw palmetto, which he did not mention at his ED visit (perhaps because no one asked whether he used any OTC or herbal medications). His primary treatment, therefore, must be directed at assessing and more successfully treating his nocturia. S.D. also likely experienced lorazepam withdrawal symptoms. The many potential risks associated with benzodiazepines in the elderly led to a valid decision to discontinue lorazepam. The choice of diphenhydramine was poor, however, not only because of limited short-term efficacy but also because of its potential to worsen both urinary symptoms and memory impairment. Clinicians must ask patients about OTC and herbal medications they may be using to self-treat their symptoms. The best treatment of sleep complaints in elderly persons is to identify any underlying treatable cause, review and identify any sleep hygiene issues, and avoid using benzodiazepines or sedating antihistamines, whose risks often outweigh any benefit.

PEDIATRIC INSOMNIA

Typical sleep need in children varies from 12 to 14 hours in children 1 to 3 years of age to between 8.5 and 9.5 hours in adolescents.[95] All major sleep disorders can occur in youth, and therefore evaluation for insomnia, RLS, PLMS, sleep apnea, and narcolepsy are needed whenever symptoms warrant. Trouble initiating and maintaining sleep are more common in children with ADHD (25%–50%) and autism spectrum disorders (44%–83%). Of infants and toddlers, 10% to 30% have bedtime sleep resistance that can be managed behaviorally with parental education. Inconsistent bedtime, falling asleep away from bed, fears, and psychiatric and medical conditions can all contribute to poor sleep in children.[95]

At least 5% to 10% of high school students have delayed sleep phase syndrome, a physiologic condition in which they do not fall asleep until between 1 and 3 AM and they awaken between 9 AM and noon. School schedules dictate earlier awakening, resulting in chronic sleep deprivation. Poll data indicate that 28% of high school students fall asleep in school at least once a week, and 14% are late or miss school because of oversleeping.[95]

Behavioral interventions to promote good sleep habits (e.g., consistent bedtime and wake-time, before-bedtime ritual) should be initiated during childhood and continued throughout adolescence to promote a lifetime of healthy sleep. No hypnotics are FDA-approved for insomnia in children and adolescents, and significant data are lacking to guide clinicians on medications to improve sleep in youth. Diphenhydramine, clonidine and melatonin are commonly used in children and some adolescents; however, the use of Z-hypnotics is also increasing, although this class has not been well studied in this population.[96]

PREGNANCY AND LACTATION

CASE 84-5

QUESTION 1: J.J. is a 32-year-old woman who is 16-week pregnant. She is moving into a new home and has been experiencing difficulty falling asleep and staying asleep. She asks whether she can take zolpidem for insomnia like she did before she got pregnant. She also asks whether melatonin or other nonprescription medications are safer.

Pregnant women have insomnia symptoms more often than their nonpregnant counterparts, and many ingest hypnotic or sedating medications. Despite frequent usage of hypnotics, healthcare providers are often reluctant to prescribe medications to pregnant woman for fear of teratogenicity. Doxylamine is FDA pregnancy category A, though this indication derived from the treatment of hyperemesis gravidarum and not insomnia.[97] Diphenhydramine is in FDA pregnancy category B and is generally considered the safest sleeping medication in pregnancy.[94] Nevertheless, a pregnant woman should only use it on an as-needed basis. Sedating antihistamines are not compatible with breast-feeding as they have the potential to dry up milk supply due to anticholinergic effects.[99] Melatonin, ramelteon, and suvorexant should not be used because of unknown risks to the fetus.[98]

Regarding the most commonly prescribed hypnotic, zolpidem, The American Academy of Pediatrics considers zolpidem compatible with breast-feeding, but the risk versus benefit should be considered on an individual basis.[98,99] Other Z-hypnotics do not have sufficient data in pregnancy and lactation to make recommendations.

Benzodiazepine hypnotics are pregnancy category D or X. They should be avoided in pregnancy due to the risk of respiratory depression, neonatal flaccidity, and feeding difficulties if given in the second and third trimester and the controversial risk of cleft palate if benzodiazepines are given in the first trimester.[100] Benzodiazepines are not recommended in breast-feeding as the risks outweigh benefits in most cases.[99]

SLEEP APNEA

Clinical Presentation

CASE 84-6

QUESTION 1: E.S., a 52-year-old man, presents to an ambulatory-care clinic complaining of chronic fatigue, low energy, excessive snoring, and overall less restful sleep. When you ask what prompted E.S. to come to the clinic, he answers: “My wife and I have been sleeping in separate bedrooms for the last 6 months. She says my loud snoring and gasping to breathe keeps her awake. I’m tired all day and find myself nodding off a lot.” His symptoms have worsened during the past year since early retirement. He has gained weight (6 feet, 220 pounds, body mass index 29.8 kg/m^2) and has developed hypertension. E.S.’s current BP reading is 145/92 mm Hg. Medications include lisinopril 10 mg and aspirin 81 mg both taken in the morning.

What are the possible causes of E.S.’s sleep disorder and why is it important for E.S. to have his problem evaluated in a sleep laboratory?

E.S. reports diminished sleep quality, excessive snoring, gasping for air, and weight gain. Although a number of causes could be responsible for E.S.’s symptoms, one of the most serious is sleep apnea. OSA is a neurologic disorder characterized by mini-episodes of breathing cessation lasting about 10 seconds. These mini-episodes generally occur multiple times in an hour. If there is a reduction in airflow but no cessation of breathing, it is termed hypopnea. The brain responds to episodes of apnea and hypopnea with mini-arousals, waking the individual to stimulate breathing.[101,102] These frequent mini-arousals prevent the individual from obtaining quality sleep by not allowing sufficient time in deep, slow-wave sleep, or REM. Obstructive sleep apnea (OSA), the most common type, may be induced when extra body weight (note E.S.’s weight gain) places pressure on the throat and uvula, narrowing the space into which air must travel; this results in the difficulty or cessation of breathing and excessive snoring. An estimated 3% to 7% of men and 2% to 5% of women meet the criteria for OSA.[102,103]

The apnea/hypopnea index (AHI), measured using polysomnography (i.e., EEG, electrooculogram, electromyogram), represents the number of episodes per hour. The AHI score accompanied by symptoms of excessive daytime sleepiness is used to diagnose OSA as follows: >5 to 14 (mild), 15 to 29 (moderate), and >30 (severe).[102]

Risk factor for OSA includes age 65 years and older, obesity (BMI >30), male gender, craniofacial anatomy that alters mechanical and neural properties of the upper airway, genetic predisposition, cigarette smoking, alcohol consumption before sleep, and comorbid conditions such as hypertension, diabetes mellitus, polycystic ovary syndrome, hypothyroidism, and pregnancy.[103] Hypertension and weight gain may be contributing to E.S.'s sleep difficulty. Untreated OSA is associated with an increased risk of hypertension, coronary artery disease, and cerebrovascular disease.[104–106] Although sleep apnea occurs in approximately 5% of women and 15% of men in the general population, it occurs in up to 40% of patients with hypertension.[104] Treatment of OSA can improve BP control and lead to more restful sleep. Of note, OSA also occurs in nonobese individuals and in all ages, including infants.[103,105] Sleep-disordered breathing, including snoring, is a significant risk factor for hypertension even in young individuals of normal weight.[104]

Overnight evaluation by polysomnography in a sleep laboratory would confirm or rule out sleep apnea and allow distinction between OSA and the less-common central sleep apnea.[102,105] Central sleep apnea results when breathing repeatedly starts and stops during sleep because the brain does not send proper signals to the muscles that control breathing (i.e., the diaphragm does not move in attempts to take in air).[105] Treatment of central sleep apnea requires continuous positive airway pressure (CPAP) as opposed to being alleviated through weight loss or anatomic manipulations. Central sleep apnea can occur along with OSA.

Drug Treatment Considerations

CASE 84-6, QUESTION 2: Results from the sleep laboratory study clearly document E.S.'s sleep problem as obstructive sleep apnea (OSA). He experiences an average of 65 apneic episodes per hour. E.S.'s weight gain and inactivity probably contribute to the problem. Both are serious, potentially life-threatening conditions. Why should E.S.'s sleeping difficulties not be treated with a hypnotic medication?

Hypnotics, alcohol, or any CNS depressant can be lethal for patients with sleep apnea and should not be prescribed for E.S. CNS depressants interfere with the mini-arousals required to stimulate breathing once it has stopped. In this case, the sleep laboratory study may have saved E.S. from a potential life-threatening breathing disorder that could have been exacerbated by a hypnotic with CNS depressant activity.

OSA can be treated by tracheostomy, nasal surgery, tonsillectomy, uvulopalatopharyngoplasty, and either nasally or orally administered continuous positive airway pressure CPAP.[98] Weight loss and CPAP therapy are the most effective treatments and must be maintained for continued therapeutic efficacy.[102,105] In CPAP, the patient wears a lightweight mask to bed each night, and a constant flow of air is provided mechanically to prevent breathing cessation and to allow for more restful sleep. Although CPAP is effective for both OSA and central sleep apnea, the results are short-lived, and apneic episodes typically reappear when CPAP therapy is stopped. Preliminary studies in individuals with nocturnal bradycardia and sleep apnea show that insertion of a permanent cardiac pacemaker significantly improved bradycardia and sleep apnea.[106] At this time, the best treatment for E.S.'s hypertension and sleep apnea is weight loss and CPAP.

CASE 84-6, QUESTION 3: If weight loss, surgery, and continuous positive airway pressure (CPAP) are all ineffective or impractical, what drug treatments are potentially effective for E.S.'s sleep apnea?

Modafinil and armodafinil agents approved for narcolepsy are also FDA-approved to treat EDS caused by OSA or shift work sleep disorder. For E.S., these agents are best used as an adjunct to nightly CPAP usage and morning administration of modafinil 200 to 400 mg or armodafinil 150 to 200 mg.[108,109] Protriptyline has dated evidence from the 1980's suggesting benefit by improving patients AHI, but it is not FDA-approved and has only been used in small numbers of patients with sleep apnea.[109]

NARCOLEPSY

Narcolepsy is an incurable neurologic disorder characterized by irrepressible sleep attacks typically occurring 3 to 5 times a day. These sleep attacks can intrude at any time during the individual's waking state. Narcolepsy may be present with or without cataplexy, although cataplexy is present in 60% to 90% of patients.[110] Cataplexy is the loss of muscle tone in the face or limb muscles and often is induced by emotions or laughter. Cataplexy can be subtle, with the patient limp and not moving, or dramatic, in which the patient collapses to the floor.[111] Hypnagogic hallucinations and sleep paralysis are other secondary symptoms not present in all persons with narcolepsy. Hypnagogic hallucinations are perceptual disturbances (i.e., auditory, visual, tactile) that occur while experiencing a sleep attack. The patient may see imaginary objects, hear sounds, or feel sensations. Sleep paralysis is a terrifying experience that can occur when falling asleep or when awakening and can last several minutes. Patients are unable to move their limbs, to speak, or even to breathe deeply. Narcoleptics learn, however, that sleep paralysis episodes are benign and brief (lasting <10 minutes). Between 10% and 20% of patients experience the tetrad of symptoms that include EDS, cataplexy, hypnagogic hallucinations, and sleep paralysis. Except for daytime sleepiness, these symptoms are thought to be expressions or partial expressions of REM sleep.[13,101,110]

Symptoms of narcolepsy often begin at puberty, but patients usually are not diagnosed until years later, in their late teens or early 20s. Early symptoms consist of excessive daytime sedation and poor sleep quality. The sleep cycle becomes progressively more erratic with frequent bursts of REM and decreased regularity of deep or slow-wave sleep. Polysomnography in a sleep laboratory is ideal to confirm narcolepsy. Sleep architecture is notably different. Instead of the 90-minute delay before REM, individuals with

narcolepsy progress directly into REM sleep.[101,110] A cerebrospinal fluid hypocretin 1 level of less than 110 pg/mL is also diagnostic for narcolepsy. Postmortem brain studies of patients with narcolepsy show 85% to 95% decrease in hypocretin-containing neurons.[111]

An autoimmune response of unknown origin is thought to damage hypocretin/orexin-secreting cells in the hypothalamus. Without functional hypocretin/orexin cells, the sleep–wake cycle is disrupted. Hypocretin/orexin is also involved in control of body weight, water balance, and temperature.[101,110]

Comparing Treatments

Optimal treatment of narcolepsy involves treating both sleep attacks and cataplexy. Schedule II controlled substances, methylphenidate and dextroamphetamine, were the first drugs used to treat narcolepsy, with 65% to 85% of patients deriving significant improvements in wakefulness. Mixed amphetamine salts are also FDA-approved for narcolepsy.[101] The mechanism of action of methylphenidate and amphetamines is related to increasing neurotransmission of dopamine and norepinephrine. Modafinil, a Schedule C-IV controlled substance, is an effective treatment with less abuse potential. Its exact mode of action is not fully understood, but it is thought to increase wakefulness through noradrenergic, adrenergic, histaminergic, GABA-modulating, glutamatergic, and hypocretin/orexin-stimulating mechanisms.[101,110] Armodafinil is the dextroenantiomer of modafinil. Its therapeutic effect, side effect profile, half-life, and abuse potential are similar to those for modafinil.[110] In summary, these stimulating drugs decrease the number of sleep attacks, improve task performance, and increase the time to fall asleep, but they cannot eliminate sleep attacks altogether. Research is underway exploring the possible use of immunosuppression at the time of narcolepsy onset. One hypothesis suggests that immunosuppression therapy during a period of pathologic immune response could prevent or reduce damage to the hypocretin system that otherwise would lead to the development of narcolepsy.[101,110]

Cataplexy does not respond to psychostimulants or modafinil but may be lessened with low doses of antidepressants. TCAs (imipramine and clomipramine) were the first antidepressants used, but protriptyline, desipramine, and SSRIs (fluoxetine, sertraline, and paroxetine) are also used.[101] SSRIs and protriptyline offer the advantage of less daytime sedation, compared with tertiary TCAs. The effectiveness of antidepressants for the treatment of cataplexy is thought to be related to REM-suppressant effects. A Cochrane Database Review concluded that insufficient evidence exists to recommend antidepressants as effective treatments for cataplexy, given that most studies are small and uncontrolled.[114] It should be recognized, however, that large-scale studies on such a rare disorder are difficult to conduct.[101] Antidepressants are not considered effective in decreasing sleep attacks.[101,110,112]

Sodium oxybate (Xyrem), a salt form of the CNS depressant γ-hydroxybutyrate, is FDA-approved for treatment of cataplexy and EDS in narcolepsy. Its therapeutic effects are related to decreased REM, improved sleep consolidation, and increased stage 3 and 4 slow-wave sleep.[101,112] Sodium oxybate must be administered twice during the night while the patient is in bed to consolidate 6 to 8 hours of sleep. In two randomized, double-blind, placebo-controlled trials, sodium oxybate 9 g/night (i.e., 450 mg at bedtime, then 450 mg 2–4 hours later), but not 3 or 6 g/night, significantly reduced the median frequency of cataplexy attacks by 69% in patients with narcolepsy, whereas 4.5 to 9 g for 8 weeks significantly reduced the median frequency of cataplexy attacks by 57% to 85% in a dose-related manner. Both trials showed 6% to 30% reduction in EDS as measured on the Epworth Sleepiness Scale and 20% to 43% reduction in daytime sleep attacks.[107] Because of a significant abuse potential, sodium oxybate is a Schedule III controlled substance. It is only available through restricted distribution, the Xyrem Success Program, which uses only one central pharmacy in the United States for dispensing.[110,111]

Mixed Amphetamine Salts and Fluoxetine

CASE 84-7

QUESTION 1: G.B., a 23-year-old man with narcolepsy, has been taking mixed amphetamine salts extended-release 60 mg in the morning for sleep attacks associated with narcolepsy, and fluoxetine 20 mg daily will be started to treat cataplexy. What are the potential risks of using both mixed amphetamine salts and fluoxetine to treat G.B.?

Anorexia, gastrointestinal complaints (abdominal pain, nausea, vomiting, diarrhea), anxiety, irritability, insomnia, and headaches are common side effects of stimulant drugs.[101] Though rare, psychotic reactions can occur in narcoleptic patients taking stimulants at any dose; however, psychosis generally resolves when the stimulant is discontinued. Stimulants, even at high dosages (e.g., 80 mg methylphenidate), usually do not bring a patient to a normal level of alertness, and sometimes nocturnal sleep is disrupted. To prevent stimulant-induced insomnia, doses should be taken before 3 PM. Tolerance to the therapeutic effects of stimulants may, however, develop in some patients with narcolepsy.[101,110,113] Drug holidays may allow the patient to recapture therapeutic benefit; however, many patients opt for an increased stimulant dose instead. Exceeding maximal recommended doses of stimulant significantly increases the risk of psychosis, substance abuse, psychiatric hospitalization, tachyarrhythmia, and anorexia according to a case–control study in 116 patients with narcolepsy taking stimulants.[101,113] Seizures have also been reported.

Fluoxetine may improve cataplexy, but it can worsen nocturnal insomnia and contribute to restlessness, headache, nausea, and sexual side effects including anorgasmia.[73,112] In addition, fluoxetine is a potent CYP2D6 inhibitor resulting in higher levels of amphetamine.[114] G.B. should be monitored closely during the initiation of fluoxetine therapy, and the amphetamine dose should be lowered by 30% to 60% to minimize side effects and prevent toxicity. The optimal therapeutic dose of fluoxetine to manage cataplexy has not been established, but low doses may be effective and minimize the risk of side effects.

Modafinil and Sodium Oxybate

CASE 84-7, QUESTION 2: G.B. experiences intolerable nervousness, irritability, and nocturnal insomnia on mixed amphetamine salts and fluoxetine. There is no improvement in cataplexy with the addition of fluoxetine. He asks about switching to modafinil and sodium oxybate. Does the combination of modafinil and sodium oxybate offer any advantage for G.B.?

Modafinil's efficacy relative to other CNS stimulants has not been adequately assessed in controlled clinical trials; however, it has less potential for insomnia and adverse CNS reactions at recommended dosages between 200 and 400 mg/day administered in the morning.[115] It also has less abuse potential compared with stimulants and is a Schedule IV controlled substance. Headache was the only adverse experience rated significantly higher than placebo in 283 patients taking the recommended dose of either 200 or 400 mg/day of modafinil. Anorexia, nervousness, restlessness, and pulse and BP increases are dose-related side effects to discuss during counseling. The maximal tolerable single daily dose may

be 600 mg/day, because 800 mg/day produced increased BP and pulse in one tolerability study.[116] Gradual dosage titration improves tolerability. Armodafinil, an active stereoisomer of modafinil, is effective at usual doses between 150 and 250 mg/day. It has a similar adverse effect profile as modafinil.[110,115]

Improved daytime wakefulness is an advantage of sodium oxybate compared with antidepressants. A controlled trial involving 278 patients showed an increase in slow-wave sleep (stages 3 and 4) and decreased nightly sleep disruption in patients taking sodium oxybate with modafinil compared with modafinil alone.[117] Sodium oxybate can be administered safely with stimulants and modafinil; however, coadministration with other CNS depressants, including hypnotic medication, is contraindicated because of the risk of respiratory depression.[111]

CASE 84-7, QUESTION 3: What counseling should G.B. receive as he switches to modafinil and sodium oxybate?

People taking modafinil should receive counseling regarding the potential for drug interactions. Modafinil induces CYP3A4 metabolism primarily in the gut and inhibits CYP2C19. Decreased levels of triazolam and ethinyl estradiol have been associated with modafinil coadministration.[118] Enzyme inhibition may also occur. Modafinil's inhibition of CYP2C19 is the proposed mechanism behind modafinil-associated clozapine toxicity.[119] Monitoring for drug interactions is crucial because modafinil and armodafinil are increasingly used for other indications, including daytime sleepiness associated with Parkinson disease, shift work, fibromyalgia, sleep apnea, fatigue associated with multiple sclerosis, and ADHD.[120–122]

Sodium oxybate should not be given to those with sleep-disordered breathing, sleep apnea, or an alcohol or substance abuse disorder.[112] Adverse effects include nausea, headache, dizziness, and enuresis. Safe coadministration of modafinil and sodium oxybate has been described in clinical trials[117]; however, cases of severe side effects including panic, psychosis, depression, and new-onset suicidal ideation have been described.[123] The risk of serious side effects versus benefits in managing cataplexy and nocturnal insomnia should be discussed with G.B. and his family. Close monitoring, particularly during the first weeks and months of treatment and when dosages are adjusted up or down, should be advised.[123] G.B. should be instructed how to properly administer sodium oxybate, drinking half the dose on an empty stomach immediately before bedtime and then setting his alarm for 4 hours later to take the midnocturnal dose.

Naps and Other Behavioral Interventions

CASE 84-7, QUESTION 4: The benefits, possible risks, and importance of regular physician assessment have been explained to G.B., and he agrees to report efficacy and adverse effects to his primary-care provider regularly. G.B. is reminded to take the medicine at regular intervals along with daytime naps. Why are naps helpful in the treatment of G.B., and what other behavioral interventions are useful in treating narcolepsy?

Strategically timed 15- to 20-minute naps taken at lunch and then again at 5:30 PM can be refreshing for patients with narcolepsy and increase their time between sleep attacks. Narcolepsy support groups are available and may help G.B. better cope with such a life-changing chronic illness. It also is important for G.B. to avoid alcohol and to regulate his bedtime and wake-up time in the attempt to normalize his sleep habits.[101,110]

Schizophrenia

Richard J. Silvia, Robert L. Dufresne, and Justin C. Ellison

CORE PRINCIPLES	CHAPTER CASES
① Schizophrenia is a persistent, heterogeneous syndrome, which includes both positive and negative symptoms. Together, these symptom clusters can have variable effects on patient quality of life, functional recovery, and prognosis. Prodromal symptoms preceding the first episode of psychosis may go unnoticed for many months. Onset of an initial psychotic episode can be an acute or insidious process that causes a significant impact on function and ability to perform activities of daily living.	**Case 85-1 (Questions 1, 2), Tables 85-1, 85-2, 85-3**
② Treatment goals will vary based upon the stage of the patient. During an acute phase, stabilization and safety are primary. During a stable phase, maintaining stability and improving functional recovery are the main goals. Treatment modalities should include both pharmacologic and nonpharmacologic methods.	**Case 85-1 (Questions 3–5)**
③ Many factors need to be considered in selecting an appropriate medication regimen for a patient with schizophrenia. Patient factors such as comorbidities, target symptoms, adherence history, personal and family history of medication response, and others need to be assessed. Medication-related factors include efficacy, safety profile, pharmacokinetics and drug interactions, and economic considerations.	**Case 85-1 (Questions 6–7, 10–11, 14–15, 22, 26–27, 30, 33), Tables 85-5, 85-6, 85-7, 85-9**
④ Adverse effects of antipsychotics are varied. They may include acute and chronic extrapyramidal movement disorders, metabolic disturbances such as weight gain and alterations in serum glucose and lipids, and other adverse effects such as sedation and orthostasis. Monitoring and appropriate interventions for adverse effects should be ongoing throughout all stages of illness to ensure continued safety and avoid medication discontinuation.	**Case 85-1 (Questions 8–9, 15–25, 27–30), Tables 85-4, 85-5, 85-6, 85-7, 85-10, 85-11, 85-12, 85-13 Figure 85-1**
⑤ Patients who do not respond to an adequate antipsychotic trial should be assessed for adherence. Long-acting injectable antipsychotics may be an option to help maintain adherence. Clozapine is the treatment of choice in patients who are refractory to at least two adequate trials of antipsychotic medications. However, clozapine does require strict adherence to blood monitoring due to the risk of agranulocytosis and carries a significant adverse effect burden.	**Case 85-1 (Questions 12–14, 26, 30–32), Tables 85-8, 85-13**
⑥ Treatment of female patients of childbearing age may require special	**Case 85-1 (Question 34)**

consideration. Untreated psychosis can result in poor self-care for the mother and inadequate prenatal care. There is also the concern for substance use, dangerous behaviors, and even suicide. Therefore, the risks and benefits of ongoing antipsychotic treatment should be carefully weighed by both the patient and the treatment team.	
⑦ Early recognition of symptoms of first-episode psychosis (FEP) and referral to appropriate multidisciplinary, comprehensive treatment services are crucial to long-term functional recovery. This population is highly sensitive to adverse effects. Antipsychotics should be titrated to the minimum effective dose to decrease duration of untreated psychosis and improve long-term prognosis.	**Case 85-1 (Question 35), Figure 85-2**

Schizophrenia is a psychiatric illness that can lead to lifelong effects on a patient's functioning. Manifesting primarily as a thought disorder, patients often have problems with perception, maintaining contact with reality, thought processing, and behavior. These symptoms can lead to a variety of impairments across many domains, including social, occupational, and emotional. Due to these symptoms, patients may require hospitalizations to help maintain or restore functionality. Treatment of schizophrenia encompasses multiple modalities, all targeted on improving a patient's symptoms and functioning, decreasing hospitalizations, and preventing morbidity and mortality.

EPIDEMIOLOGY

Schizophrenia is a heterogeneous, genetically linked "spectrum" disorder that affects 0.7% of the population.[1] It is the ninth leading cause of disability in the world,[2] being found in all cultures and races. While often incorrectly assumed to be more common in men, there is no gender difference in the incidence of the illness. However, the onset of schizophrenia tends to occur between the ages of 18 to 25 in males and from 26 to 45 years old in females, and usually persists for a lifetime.[3] Overall, more severe symptoms are generally seen in males versus females.

ECONOMIC BURDEN

The economic burden of this devastating disease and its treatment is enormous.[4–7] In one estimate from 2002, US costs for schizophrenia totaled $62.7 billion. This included $30.3 billion in direct healthcare costs (of which medications accounted for $5.0 billion) and $32.4 billion in indirect costs, such as lost productivity and other costs incurred to the healthcare system.[3] Although progress has been made in treating the symptoms of schizophrenia and restoring moderate levels of functioning, there is as of yet no cure. As many patients present with an early age of onset, the lifetime burden of illness can be great. Many patients will need repeated hospitalizations and, when not hospitalized, will require significant outpatient services and treatment. Additionally, many patients require supportive living situations, either in facilities designed for these services or with family members, increasing the financial burden on their families as well.

ETIOLOGY

Multiple neurotransmitter and physiologic mechanisms have been hypothesized to explain the complex etiology of schizophrenia. Many theories on the role aberrant neurotransmitter systems play in schizophrenia are derived from the pharmacologic actions of the medications used to treat the illness in addition to direct analysis from biologic samples. Findings on neurologic scans and other measurements of neuroanatomy are also not consistent across patients to allow for these methods to be reliably employed in making a diagnosis of schizophrenia. Genetic markers have more recently been explored with advances in genetics, but these too are not all-encompassing. In this section, chemical, biologic, and environmental bases of schizophrenia will be presented.

Genetic and Environmental Risk Factors

A genetic component to schizophrenia has been hypothesized since the observation that family members of patients are more prone to develop schizophrenia than the general population. Rates of schizophrenia among family members vary (anywhere from 2% to 50%) based upon the relationship to the patient with schizophrenia.[1] Children born to parents who both have schizophrenia are affected in 40% to 60% of cases. Siblings of patients with schizophrenia, including dizygotic twins, are also affected in 10% to 15% of cases. However, monozygotic twins develop schizophrenia approximately 50% of the time if their twin also has the illness. Second- and third-degree relatives of patients more closely approximate the general population, but still develop the illness approximately 2% to 5% of the time. Many genes are thought to play a role in schizophrenia, but no gene has been found to be universal across patients. This finding suggests multiple genes may be involved in the etiology of schizophrenia. Although a genetic role appears to exist, it does not explain how all patients develop the illness. Approximately two-thirds of patients have no known familial history of the illness; therefore, other factors must play a role in these patients.[1] Certain environmental exposures in early development are associated with development of schizophrenia. Maternal infections, in particular influenza, stress, and malnutrition during the first and second trimesters, have shown a link to the child developing schizophrenia. Fetal or infant hypoxia during delivery or in the first few months of life has been shown to double the risk of schizophrenia. Childhood trauma and substance abuse have also been linked to the development of schizophrenia.

Pathophysiology

The actual nature of the pathophysiology of schizophrenia is both unknown and complex. It may be more appropriate to conceptualize it as a syndrome that may involve many different underlying disease mechanisms.[8] Although numerous deviations in brain structure and physiology have been noted, such as decreased gray matter volume, whole-brain volume, and enlarged ventricle size,[9] most treatments focus on antagonism of presupposed increased activity at dopamine-2 (D_2) receptors. The potency of typical antipsychotic medications has correlated with their antagonism of these receptors, although some atypical antipsychotics, such as clozapine, are extremely effective with a lesser degree of D_2 receptor blockade.[10] The initial dopamine hypothesis of schizophrenia theorized that positive symptoms of schizophrenia (e.g., conceptual disorganization and hallucinations) result from abnormally increased activity in the mesolimbic dopamine neurons and that negative and affective symptoms of schizophrenia result from subnormal mesocortical dopamine neuronal activity.[11] This remains a clinically useful, albeit simplistic, conceptual framework because many dopamine agonists tend to increase positive symptoms and oppose the effects of antipsychotics. The relation of negative symptoms to dopamine neurotransmission is even more complex. Some suggest that decreased dopamine in frontal areas is linked to negative symptoms and increased dopaminergic neurotransmission in striatal areas results in positive symptoms.[12] To explain the efficacy and lack of movement adverse effects, prolactin elevation, or secondary negative symptoms of antipsychotics such as clozapine and quetiapine, one theory proposes that they have a faster dissociation from the D_2 receptor than other antipsychotics.[13] It has also been suggested that 65% of D_2 receptor occupancy predicted response and 78% predicted extrapyramidal adverse effects.[14]

More recent thinking suggests involvement of glutamate and GABA, which are intertwined with the disturbances in dopaminergic neurotransmission.[15] While speculation that glutamate was involved in the pathophysiology of schizophrenia started in the 1980s, the demonstration that N-methyl-D-aspartate (NMDA) receptor antagonists best replicated all the major schizophrenic symptoms such as the positive, negative, and cognitive ones in healthy subjects lent credence to the "NMDA receptor hypofunction hypothesis." Because negative symptoms and cognitive deficits are not treated by D_2 receptor antagonists nor worsened by dopamine agonists, a theory that involves early disruption of glutamine transmission in schizophrenia is an appealing hypothesis. Also, unlike subcortical dopaminergic dysfunction, pathologic brain changes such as widespread dendritic and spine dysplasia along with cortical atrophy could possibly relate to NMDA receptor hypofunction.[16] Excitatory neurotransmission in the brain is predominantly glutamatergic, and glutamate dysfunction could possibly relate to dopamine dysfunction both in its prodrome and later on in the course of the illness.[17] In schizophrenia, it can be considered that dopaminergic changes are a final end mechanism where antipsychotics work in which increased mesocortical dopamine turnover and overactive mesolimbic dopaminergic over activity result from other preceding neurotransmitter changes.[10]

Gradual progressive NMDA receptor hypofunction would also be consistent with the altered neuroanatomy of schizophrenia.[18] Decreased brain volume in schizophrenia has been noted since the 1920s, and there are more recent findings to believe that there are changes in brain structure with reductions in the volume of certain areas of the brain as well as changes in connectivity.[8] Enlargement of cerebral ventricles is a typical finding in schizophrenia, and reduced dendritic spine density in cerebral cortical pyramidal neurons where NMDA subtypes of glutamate receptors are present has been noted.[19] Some of these neuroanatomic differences include impaired white matter integrity as well as reduced volume of gray matter in inferior parietal, prefrontal, superior, and medial temporal, thalamic, and striatal regions.[20] There are also a number of studies suggesting the importance of these white matter abnormalities in schizophrenia to dysconnectivity between functional tracts.[21]

CLINICAL PRESENTATION

Historical Concept of Schizophrenia

Schizophrenia was first characterized as "dementia praecox" by early psychiatrists Arnold Pick and Emil Kraepelin in the late 19th century,[22] and was described by Bleuler as a "disintegration of psychic functions."[23] Historically, schizophrenia has been a disease characterized by progressive deterioration of the brain. Although modern findings seem to corroborate this viewpoint, few patients with schizophrenia show the progressive incremental loss of function that is characteristic of neurodegenerative illnesses.[24] The demonstrated effectiveness of dopamine receptor antagonists in the treatment schizophrenia[25] resulted in the disorder being conceptualized as a heterogeneous syndrome characterized by D_2 receptor hyperfunction[26] predominately in mesolimbic regions of the brain.

Diagnosis and Differential Diagnosis

The diagnosis of schizophrenia in the recently introduced DSM-5 requires that an individual has at least two persistent symptoms such as delusions, hallucinations, disorganized speech, or behavior over a 6-month period.[27] Also, in the DSM-5, subtypes of schizophrenia, such as paranoid or undifferentiated, have been removed. These distinctions were not clinically useful because patients often displayed characteristic symptoms from each subtype at various times in their illness, or even concurrently.[27] Patients presenting with either manic or depressive symptoms concomitantly with their typically schizophrenic ones are still diagnosed as having schizoaffective disorder (Table 85-1).

Numerous disorders are characterized by psychosis during exacerbation (Table 85-2). Schizophrenia differs in its presentation from bipolar disorder in that there are prominent signs of conceptual disorganization and hallucinations. Prominent "negative" symptoms such as apathy, avolition, poverty of speech, and emotional blunting may also be present. Schizoaffective disorder, bipolar type, may pertain to patients who present with both positive schizophrenic symptoms and either mania or depression. It is not uncommon for patients with schizophrenia to suffer from secondary depression at various times during the course of their illness as well.[28] Suicide in these patients is not uncommon.[29]

Table 85-1

DSM-5 Criteria for Schizophrenia

A. Characteristic Symptoms
Two (or more) of the following, each present for a significant portion of time during a 1-month period (or less if successfully treated). At least one of these must be 1, 2, or 3: 1. Delusions 2. Hallucinations 3. Disorganized speech (e.g., frequent derailment or incoherence) 4. Grossly disorganized or catatonic behavior 5. Negative symptoms (i.e., restricted affect or avolition)
B. Functional Disturbance
For a significant portion of the time since the onset of the disturbance, level of functioning in one or more major areas, such as work, interpersonal relations, or self-care, is markedly below the level achieved prior to the onset (or when the onset is in childhood or adolescence, there is failure to achieve expected level of interpersonal, academic, or occupational functioning).
C. Duration
Continuous signs of the disturbance persist for at least 6 months. This 6-month period must include at least 1 month of symptoms (or less if successfully treated) that meet Criterion A (i.e., active-phase symptoms) and may include periods of prodromal or residual symptoms. During these prodromal or residual periods, the signs of the disturbance may be manifested by only negative symptoms or by two or more symptoms listed in Criterion A

present in an attenuated form (e.g., odd beliefs, unusual perceptual experiences).
D. Schizoaffective Disorder and Mood Disorder Exclusion
Schizoaffective disorder and depressive or bipolar disorder with psychotic features have been ruled out because either (1) no major depressive or manic episodes have occurred concurrently with the active-phase symptoms or (2) if mood episodes have occurred during active-phase symptoms, they have been present for a minority of the total duration of the active and residual periods of the illness.
E. Substance or General Medical Condition Exclusion
The disturbance is not attributable to the physiologic effects of a substance (e.g., a drug of abuse, a medication) or another medical condition.
F. Relationship to a Neurodevelopmental Disorder
If there is a history of autism spectrum disorder or a communication disorder of childhood onset, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations, in addition to the other required symptoms of schizophrenia, also are present for at least 1 month (or less if successfully treated).

Differential Diagnosis for Schizophrenia

Drug-induced Psychoses
Alcohol (or other sedative-hypnotics) Amphetamine (or other stimulant)
Cocaine
Cannabis (marijuana)
Phencyclidine (PCP)
Lysergic acid diethylamide (LSD)
Anticholinergics (especially in overdose)
Anabolic and Corticosteroids
Other Psychiatric Disorders
Major depressive or bipolar disorder with psychotic features Schizoaffective disorder
Schizophreniform disorder and brief psychotic disorder
Delusional disorder
Paranoid, Schizoid, or Schizotypal personality disorder
Obsessive-compulsive disorder and body dysmorphic disorder
Post-traumatic stress disorder
Autism spectrum disorder or communication disorders

Adapted from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders. 5th ed. Arlington, VA: American Psychiatric Publishing; 2013:87–122, with permission.

In new-onset psychosis, the treating clinician should be careful to rule out drug-induced (i.e., amphetamines, cocaine, “k2” synthetic cannabinoids, anticholinergics, LSD, phencyclidine) causes. Corticosteroids may induce a manic type of psychosis, whereas anabolic steroids may provoke a more aggressive type of psychotic presentation. Obtaining a toxicology screen may be prudent. A patient can have a brief psychotic disorder that comes on suddenly, last for up to one month, and remit with no recurrence of symptoms. A patient presenting with signs and symptoms of schizophrenia between one to 6 months is said to have a schizophreniform disorder. Furthermore, depression can present with mood congruent auditory hallucinations (often deprecatory) and delusions. Finally, patients with cluster A personality disorders can show some isolated symptoms such as paranoia or blunted affect, but do not meet full criteria of schizophrenia.[30]

Hallmark/Target Symptoms

The symptoms of schizophrenia are generally organized into two main domains: positive and negative (Table 85-3). Positive symptoms are usually what the public perceives when thinking about schizophrenia: hallucinations, delusions, and disorganization. Hallucinations can affect any of the five senses, but auditory are the most common. Delusions are fixed false beliefs that are persistent despite evidence to the contrary. Delusional subtypes include persecutory, erotomanic (e.g., delusion of love), delusions of grandeur (having special abilities), or somatic (i.e., delusion of being pregnant in context of negative pregnancy tests). Disorganization can manifest in the patient’s speech, thought patterns, or behaviors. Some examples of disorganized speech can include made-up words (neologisms), rhyming words (clang speech), speaking words in a sentence in incorrect order (word salad), and repeating words said to them (echolalia). Examples of disorganized behaviors can include repeating the same activity needlessly (perseveration), repeating someone else’s actions (echopraxia), dressing oddly for the setting or season of the year (wearing winter clothes in summer), or other odd behaviors based upon the setting the patient is in. Negative symptoms of schizophrenia include apathy, avolition, blunted affect, and poverty of speech.[31] A decreased ability to experience pleasure (known as anhedonia) and social withdrawal can lead to significant functional impairment, even when positive symptoms are relatively absent in a patient. During acute episodes, positive symptoms may predominate, whereas over the long term it may be negative symptoms that are more troubling and disabling to a patient. A third domain of cognitive symptoms can also present in schizophrenia. Symptoms include concrete thinking, inattention, problems with memory, learning and executive function, as well as conceptual disorganization.[32] When these cognitive symptoms are combined with negative symptoms over the patient’s lifespan, significant impairment in function may result. Comorbid depression is also common in schizophrenia[33] and can be difficult to treat,[28,34,35] and symptoms can be predictive of relapse.[36,37] Depressive symptoms may be overlooked in the face of overwhelming positive symptoms, or confused with negative symptoms.

Table 85-3

Positive and Negative Symptoms of Schizophrenia

Positive	**Negative**
Hallucinations (auditory, visual, or other senses)	Diminished emotional expression (body language)
Delusions (persecutory, paranoid, grandiose, etc.)	Avolition/psychomotor retardation
Disorganized thinking/speech	Alogia (decreased speech)
Grossly disorganized or abnormal motor behavior (including catatonia)	Anhedonia (decreased ability to feel pleasure)
Unusual behavior	Asociality (lack of socialization)
Combativeness, agitation, and hostility	Affective flattening
Ideas of reference	

CASE 85-1

QUESTION 1: J.J., a 26-year-old, single female college student, was brought to the emergency department of the local hospital by her school's campus security at 3 am after she was found running naked through the campus screaming "They're after me and won't leave me alone! They keep telling me to run and hide!" J.J.'s roommate has accompanied her with the security officers.

History of Present Illness: J.J. is not a good historian, but her roommate is willing to provide information to help. When asked questions, J.J. provides indirect, tangential answers, repeating her concerns of "they are after me." When asked who is after her, she responds "the FBI of course! They think I'm a spy- but I am a spy for the CIA!" Various times during the interview, J.J. is found talking to someone not in the room. When asked about that, she says she hears the voice of her CIA supervisor through the "transmitter in my head" and needs to respond. She said the transmitter also allows her to read other people's minds, which is how she spies for the CIA. J.J.'s roommate states that JJ has been acting erratic for the past couple semesters, but she thought it was just from an online video game they had been playing. Once, she returned to their dorm room and J.J. had barricaded the door from the inside with furniture so no one would find

---

her. She states J.J. is often up late at night on her computer, which she says is to "look for traces of the enemy spies."

Medical History: J.J. has no significant medical or psychiatric history. She has never been hospitalized or treated for any psychiatric condition in the past. Her roommate has known her since they started college together 3 years ago, and they have been roommates for the past 2 years. The roommate says J.J. was fairly normal—quiet and shy, getting good grades—until the unusual behavior started almost a year ago after they returned from summer break. She says J.J.'s behavior has gotten increasingly unusual and erratic since then.

Psychosocial History: A call to J.J.'s mother finds that her father has a history of alcoholism and domestic violence which led to their divorce when J.J. was 14. J.J.'s paternal uncle has been diagnosed with schizophrenia and has been hospitalized multiple times over his lifetime. J.J.'s mother says she has always been a very good student, but not very social when in high school, tending to isolate from her classmates. She screamed at them one day in school saying she would defend herself if they carried out their plans and the police were called. No charges were filed and J.J. was entered into the school's anger management program, to which she never showed up. J.J.'s roommate states she only drinks socially at occasional parties and denies any illicit substance abuse.

Physical Examination/Laboratory Tests: J.J.'s physical examination shows no significant or contributory findings other than some bruising on her knuckles from punching the walls. J.J. states this is from "fighting off the FBI agents" when they find her. Laboratory tests, including complete blood count (CBC), SMA-28 panel, and liver and thyroid function tests, all return normal. A urine drug screen returns all negative results. No other tests were ordered.

Mental Status Exam: Appearance and Behavior: J.J. is a tall, average build, neat but casually dressed young woman who appears her stated age. She shows signs of paranoia and agitation as she is constantly looking around the room and pacing. She constantly asks to be released "before they find me." Mood: J.J. is anxious and concerned that the "FBI will find me" and prevent her from completing her mission. Affect is animated due to his level of agitation. She does not report any depressive ideation. Memory: Long-term memory appears to be intact (confirmed by roommate) but patient will not cooperate with recall tests of immediate- and short-term memory as "this is a waste of time and I need to be released." Orientation: J.J. is oriented to person, place, time, and situation. Thought Content: J.J. is fixated on needing to leave in order to complete her mission. She is convinced the longer she stays the more likely the FBI will find her here and she will "need to fight my way out." She also states she is trying to use her implanted transmitter to read the thoughts of the people in the room. She denies any suicidal or homicidal ideation. She accuses you of keeping her there to help the FBI. Thought Process: J.J.'s speech is highly disorganized such that she can be difficult to comprehend. Perception: J.J. is clearly responding to internal stimuli and most likely auditory hallucinations. She also keeps asking the staff whether something is burning and where the smell is coming from. Insight and Judgment: J.J. has poor insight into her symptoms and mental state, and will most likely require inpatient hospitalization for psychosis.

Provisional diagnosis: psychotic episode, most likely due to schizophrenia.

What hallmark symptoms of schizophrenia is J.J. presenting with at this time? How might these symptoms be used in monitoring treatment?

J.J. currently presents with a number of hallmark symptoms of schizophrenia. She has olfactory as well as auditory hallucinations (hearing her CIA supervisor and others), delusions (she works for the CIA and the FBI is after her, having a transmitter in her head), and magical thinking (she can read people's thoughts). She shows conceptual disorganization in her speech. She is also agitated and uncooperative, and has acted out on her delusions by getting into arguments with people she feels are from the FBI. These symptoms should begin to decrease and subside with time as effective medication treatment is utilized, allowing us to determine whether J.J. is responding appropriately.

CASE 85-1, QUESTION 2: What information from J.J.'s history also contributes to a diagnosis of schizophrenia? What is the prognosis for J.J.?

Although J.J. has had no previous psychiatric treatment, she is in the age range for an initial psychotic episode of schizophrenia (late teens to mid-20s). J.J. has been showing increasingly unusual behavior for over 6 months, and possibly up to a year according to her roommate, with more drastic changes more recently. Prior to this, J.J. did show some prodromal symptoms, most notably some difficulty interacting with peers while in high school and isolating herself. There is also a family history of schizophrenia (paternal uncle) and alcoholism (father). J.J.'s prognosis is variable, because her young age of onset, family history of schizophrenia, and unstable home environment at a young age indicate a poor prognosis, but her relatively high baseline functioning and intelligence (she did very well in high school and is currently in college) would increase the chances for a better long-term outcome. As J.J. is early in her illness, it will take time to better determine her long-term prognosis more clearly.

Typical Course of the Illness and Prognosis

The course of schizophrenia can vary between individuals. However, a common pattern entails a premorbid phase with possible signs of cognitive, motor, and social deficits in childhood at 12 years old or under, a prodromal phase during adolescence and young adulthood (12–18 years old) including a functional decline with brief or attenuated positive symptoms, and then an active phase which includes florid positive symptoms as part of psychosis.[20,38] An improved prognosis is associated with female gender, a preponderance of positive and mood symptoms versus negative symptoms, rapid onset of symptoms, older age at symptom onset, and high premorbid functioning.[39,40]

Generally, the negative (or deficit) and cognitive symptoms of schizophrenia predominate earlier in the development of the disorder. Florid positive symptoms usually emerge between 18 to 25 years of age in men and 20 to 30 years of age in women.[22] During the prodromal phase, patients may show what resembles negative symptoms: blunted affect, decreased motivation and energy, social withdrawal, and others. Cognitive symptoms may also present, such as poor concentration and memory, which may manifest as declining school or work performance. Low-level positive symptoms may also be seen, mostly in the form of disorganized thinking. Other symptoms such as depression, anxiety, or irritability may also present. Often these symptoms will go unrecognized in adolescents and be mistaken for anything from puberty, relationship problems, or drug abuse. This phase may last from weeks to years and often is not attributed to schizophrenia until the first psychotic episode. In many instances, patients will convert to a full schizophrenia diagnosis with more significant positive symptoms and go months or more before receiving treatment. This delay may affect the long-term prognosis of the illness as early treatment can decrease later morbidity as response to treatment in first-episode schizophrenia in critical.[41]

After an active phase of schizophrenia, which can last a large part of adulthood, patients usually enter a residual phase of chronic disability. Later in this phase, symptoms may become somewhat similar to the prodromal phase. As the disease progresses, residual symptoms may increase between episodes and make normal day-to-day functioning difficult. As the patient ages, the medical complications of schizophrenia, treatment-emergent metabolic syndrome, and effects of tobacco use increasingly take hold.[38] Patients with schizophrenia have a life expectancy 9 to 10 years shorter (or more by some estimates) than the average population.[42] The disease often becomes characterized by a preponderance of negative symptoms and cognitive deficits in those living into the later years.[27] However, with early intervention and support, many patients can achieve symptom control and lead meaningful and fulfilling lives.

TREATMENT

Schizophrenia is generally considered a chronic, lifelong illness consisting of varying periods of illness severity, with resulting effects on patient functionality. Although pharmacotherapy can have positive effects on reducing symptoms of the illness and improving functionality, there are often symptoms that may not respond adequately to treatment. In addition, despite adequate treatment, patients may have relapses of their illness, leading to acute psychotic episodes needing more intensive treatment. Treatment is therefore usually lifelong and is often multidisciplinary in its approach, consisting of pharmacotherapy, psychosocial therapy, case management, and other methods.

Goals of Treatment

The overall goal for the treatment of schizophrenia is to reduce the symptoms of the illness in order to improve patient functionality and quality of life. Depending upon the patient's current level of acuity, the specific goals for the patient at that time may vary. Although similar pharmacotherapy and nonpharmacotherapy methods may be employed across the spectrum of severity of schizophrenia, they may be utilized differently. Patients are generally described as being in one of three treatment phases according to the American Psychiatric Association: acute, stabilization, and stable.[27] These phases are not static, and patients can move between these phases frequently over the course of their illness.

ACUTE PHASE

The primary goal of treatment in the acute phase of illness is to reduce the threat of harm to the patient or others. Patients experiencing acute psychosis will present with prominent positive symptoms and exhibit disorganized speech and/or behaviors. Negative symptoms and suicidal ideation may also be more pronounced and severe. This will often require a higher level of care than the outpatient setting can provide and necessitate inpatient psychiatric hospitalization where the patient is stabilized.

Medications, including short-acting injectable antipsychotics and benzodiazepines, are usually required to target agitation in acute psychosis. However, psychosocial interventions and collaboration with family and caregivers for collateral information are also crucial in this phase of illness.[43] Antipsychotic should be initiated as soon as clinically possible to decrease duration of untreated psychosis and improve long-term prognosis.[44]

The reason for psychiatric decompensation should be ascertained through patient report and collateral information (e.g., caregiver insight, pharmacy fill records). Schizophrenia has a variable course. Exacerbations can occur even on a therapeutic regimen in the context of psychosocial stressors, illicit substance use, and other reasons. However, if the exacerbation was due to nonadherence, the reasons should be explored with the patient. If the patient was nonadherent due to intolerable adverse effects, a lower dose or alternative medication could be considered. If difficulty remembering to take medication was the issue, a long-acting injectable formulation could be considered. In either scenario, the decision to initiate or change the antipsychotic should be based on patient preference, prior history of response, tolerability, and relevant medical comorbidities.

STABILIZATION PHASE

The aim during the stabilization phase is to promote continued recovery, maintain symptom control, begin facilitating referrals for supportive outpatient services, and reduce adverse effects and likelihood of future relapse. The patient and involved caregivers should be educated on the timeline of symptom response, possible medication adverse effects and their management, importance of adherence, and recognizing early signs of symptom recurrence. Risk for relapse is highest within the first 6 months post initial psychotic episode. Therefore, medications should be maintained for at least 6 months at the dose found to be effective in reducing positive symptoms during the acute phase.[45] Patients and caregivers should be counseled that partial response, such as decreased volume, intensity, or frequency of auditory hallucinations, should not be considered a failure of treatment. Residual symptoms can persist beyond the acute and stabilization phases, but may remit with maintenance treatment.

STABLE PHASE

The main focus of the stable phase is quality of life and functional recovery. This is achieved through ensuring optimized treatment of symptoms, minimizing risk of adverse effects, and psychosocial interventions. The question of how long antipsychotics need to be continued is often raised by patients. Antipsychotics have been shown to significantly reduce rates of relapse at one year versus placebo.[46] Therefore, maintenance antipsychotic treatment should be continued for at least one year in all patients recovering from a psychotic episode. Caveats to this include intolerable adverse effects to the antipsychotic or uncertainty of the diagnosis of schizophrenia. Lifelong treatment is recommended in patients who have experienced multiple episodes of psychosis, at least two episodes within 5 years, or those who pose a significant risk to themselves or others when symptoms are left untreated. A slow, cautious taper off antipsychotics can be considered after one year in first-episode patients with close follow-up established.[45] Routine monitoring for adverse effects, especially EPS and metabolic syndrome, is recommended during the stable phase. Patients may not connect an adverse effect to their medications, particularly a somatic complaint when the main therapeutic target of their medication is in the CNS, so education and close follow-up are needed. The nonpharmacologic aspects of treatment are an important adjunct to pharmacologic management in functional recovery. Psychosocial interventions include assertive community treatment teams for high-risk patients, vocational training or supported employment, and cognitive behavioral therapy. Adjunctive treatments for comorbid conditions, such as depression and anxiety, should also be addressed during this phase.

Nonpharmacologic Interventions

In addition to medication-based treatments, there are a variety of nonpharmacologic treatments that have also been found to be useful in the treatment of schizophrenia. Most patients will benefit

from a combination, multidisciplinary approach to treatment. Treatment guidelines for schizophrenia recommend a treatment plan that includes both pharmacologic and nonpharmacologic treatment.[45] Nonpharmacologic interventions may include individual or group psychological therapy as well as family therapy, cognitive skills training, vocational skills training, and others. When utilized, these interventions have increased patient understanding of their illness, decreased patient symptoms and relapse rates, and improved social and occupational functioning.

Selection of one of these interventions is based upon the patient’s level of acuity and specific needs, but should be considered during all phases of the illness. For example, a patient having an acute episode of psychosis might not be appropriate for cognitive or vocational skills training, but might benefit from individual therapy to help develop insight into their illness and understand why they are being treated. During an acute phase, other, more simplistic interventions can also play a key role. For example, inpatient settings may utilize techniques to minimize stimulation or stress for patients, particularly those who are agitated or potentially aggressive. Group therapy sessions can assist patients with social interaction, something that might be difficult for many patients.

As the patient moves from an acute phase into a stabilization or stable phase, addition of skills training could be considered. Many patients will have lingering negative and cognitive symptoms that might not fully respond to pharmacotherapy. Cognitive skills training can assist with both of these areas, helping patients to overcome functional deficits arising from these symptoms. Vocational skills training can teach patients a variety of skills to prepare them to re-enter the workforce, even if only in a minor role.

Family therapy can be helpful for both patient and family. Many families are greatly affected when a family member is diagnosed with schizophrenia. Improving family understanding of the illness and how to interact appropriately with the patient can be of great impact to all involved. Additionally, the stress on the family can be mitigated through family therapy and assistance programs.

Pharmacists can also play a role in nonpharmacologic treatment by assisting with patient education (particularly in regard to medications) and patient adherence to medication. Assistance with adverse effects to medications is also an area in which pharmacists can play a role.

CASE 85-1, QUESTION 3: What are the management goals for J.J.?

First and foremost is to ensure J.J.'s safety. While not serious, she has already injured herself by punching her walls. She is also very argumentative due to her paranoia, which could inadvertently lead to an altercation. A reduction in J.J.'s symptoms is also desired, ideally leading to an improvement in her functionality and insight into her illness. In light of J.J.'s symptoms and lack of insight into her illness, she will most likely require hospitalization to both ensure her safety and effectively treat her symptoms.

CASE 85-1, QUESTION 4: What nonpharmacologic treatment would you recommend for J.J. at this time?

During the acute phase, especially while J.J. still displays prominent positive symptoms, nonpharmacologic treatment should center on stress reduction and education on her illness. By reducing her stress, the goal is that J.J.'s paranoia and agitation will decrease, allowing her to more meaningfully engage in treatment. Illness education can be accomplished through both individual and group therapy and education sessions. As J.J. moves from an acute phase into a stabilization phase, more specific interventions can be started, such as vocational skills training, depending upon her need and her level of functionality at that time.

J.J. would also benefit from medication education, such as from a pharmacist, once she is more stable in order to better understand her medications and any potential adverse effects.

CASE 85-1, QUESTION 5: How should J.J. be best communicated with by the staff treating her at this time? What recommendations would you provide her family and friends for communicating with her, both currently and once she is sent home?

The staff should attempt to use methods of communication that will not agitate J.J.

or increase her paranoia. This includes both verbal and nonverbal (body language) communication. If J.J. does become paranoid or agitated, she should be approached with calmness in an attempt to deescalate the situation. Directly challenging her hallucinations and delusions will most likely only increase her paranoia, so this should be avoided. If possible, speak to J.J. during times when she is calm and having fewer symptoms and inquire about what methods she would prefer employed to calm her down when she does become agitated, such as being put in a room alone to relax, listening to music, conversing with a staff member, etc.

J.J.'s family and friends should be educated about her illness to help them understand how to avoid upsetting her and potentially increasing her symptoms, especially during the acute phase. Avoidance of topics that would make her upset would also be appropriate. Once J.J. is sent home, they should interact with her as they normally would, but being aware that her symptoms could return at any time and they should be vigilant for this. If they observe any significant change in her status, they should attempt to get J.J. to a medical provider to evaluate her situation.

Assessment

The issues and conducting a differential diagnosis of schizophrenia have been previously discussed above. Patients are assessed for the severity of their symptomatology after diagnosis using information from direct assessment via patient interview, discussions with family and friends of the patient as well as treatment staff, and review of the medical records. There are no laboratory tests to measure progress in schizophrenia at this time. It is important to obtain laboratory baseline monitoring tests that can be relevant for the differential diagnosis and for the monitoring of adverse effects of medications. First, it is important to obtain a complete psychiatric and medical history including all past medications. It is suggested that patients receive a physical examination and that clinical laboratory tests of thyroid, liver, and renal function be obtained. A complete cell blood count with differential as well as a urinalysis and urine toxicology screen (if drug abuse is suspected) should be obtained. A fasting blood glucose and serum hemoglobin A1c (HbA1c) level is useful considering the high rate of type 2 diabetes prevalent in patients with schizophrenia. Obtaining an electrocardiogram is also useful, especially if the patient is over 40 years of age or likely to receive a medication with significant QT_c prolongation effects.

The most prevalent way to record the results of a clinical assessment in the patient with schizophrenia would be via the mental status examination.[47] If a patient is to be treated in a clinical study, schizophrenic symptomatology may be assessed using the Positive and Negative Symptoms Scale (PANSS),[48] the Brief Psychiatric Rating Scale (BPRS)[49], and Clinical Global Impression (CGI) scale. Adverse effects to antipsychotic treatment can be assessed using instruments such as the Abnormal Involuntary Movements Scale (AIMS) or Dyskinesia Identification System

Condensed User Scale (DISCUS) for tardive dyskinesia,[50] or the Simpson-Angus Rating Scale for drug-induced parkinsonism, and general adverse effects can be recorded via the Treatment

---

Emergent Symptoms Scale (TESS).[51] These are all scales suitable to measure the severity of these symptoms, but are not used as diagnostic instruments.

Pharmacotherapy Interventions

ANTIPSYCHOTICS

Classification and Nomenclature of the Antipsychotics

The first effective antipsychotic medication used in western medicine was chlorpromazine, a low-potency sedating “typical” antipsychotic first developed in 1951 to augment anesthesia, and was termed by its inventor Laborit to be a “vegetative stabilizer.”[52] While its introduction resulted in a sharp decrease in the number of hospitalized patients with schizophrenia, it was imperfect in that it caused adverse effects such as drug-induced parkinsonism, acute dystonias, sedation, anticholinergic effects, and orthostasis. The knowledge that D_2 antagonism was a key in making effective agents for treating schizophrenia led to the development of a plethora of new agents, some of which were much more specific in selectively antagonizing these receptors. The medications with greater dopamine specificity tended to have fewer effects on other neurotransmitter systems (Fig. 85-1). Therefore, these “high-potency” first-generation antipsychotics (FGAs), such as haloperidol or fluphenazine, were less likely to cause related adverse effects such as sedation, increased appetite, dry mouth, constipation, and orthostasis than “low-potency” agents, such as chlorpromazine and thioridazine. However, high-potency FGAs have a greater propensity to cause acute dystonias and drug-induced parkinsonism than the low-potency agents. The middle-potency agents, such as loxapine, molindone, and perphenazine, have more moderate adverse effects. These medications have other unique properties that differentiate them. For example, molindone was found to induce modest weight loss,[53,54] and loxapine was thought to be somewhat atypical in its effects on serotonergic receptors. These recognized properties helped lead to the development of the second-generation antipsychotics (SGAs) or “atypical antipsychotics.”[55]

The first SGA, clozapine, differed dramatically in its pharmacology from previous agents. It is a very potent antagonist of serotonin-2a (5-HT_{2a}) and serotonin-2c (5-HT_{2c}) receptors. It was later determined that the ability to antagonize serotonergic receptors was critical to creating other new “atypical” agents that could act in a manner similar to clozapine, but without its critically serious adverse effect profile. Clozapine was shown to have robust effectiveness in treating resistant schizophrenia[56], to cause agranulocytosis in about 1% to 2%[57] and to induce seizures in 6% of those taking it at higher dosages,[58] possesses nuisance side effects such as sialorrhea and constipation, and is even associated with myocarditis.[59–61] Because clozapine is restricted to only the treatment-resistant or antipsychotic-intolerant patient, newer agents that were introduced, such as risperidone, olanzapine, quetiapine, and ziprasidone, were used with initial excitement. This excitement was tempered with caution when it was discovered that these agents could also be associated with obesity, hypertriglyceridemia, and even the onset of type 2 diabetes mellitus. Later, somewhat unique agents were introduced with possible advantages such as aripiprazole, lurasidone, paliperidone, iloperidone, asenapine, brexpiprazole, and cariprazine. The terms FGA and SGA will be utilized for clarity throughout the chapter.

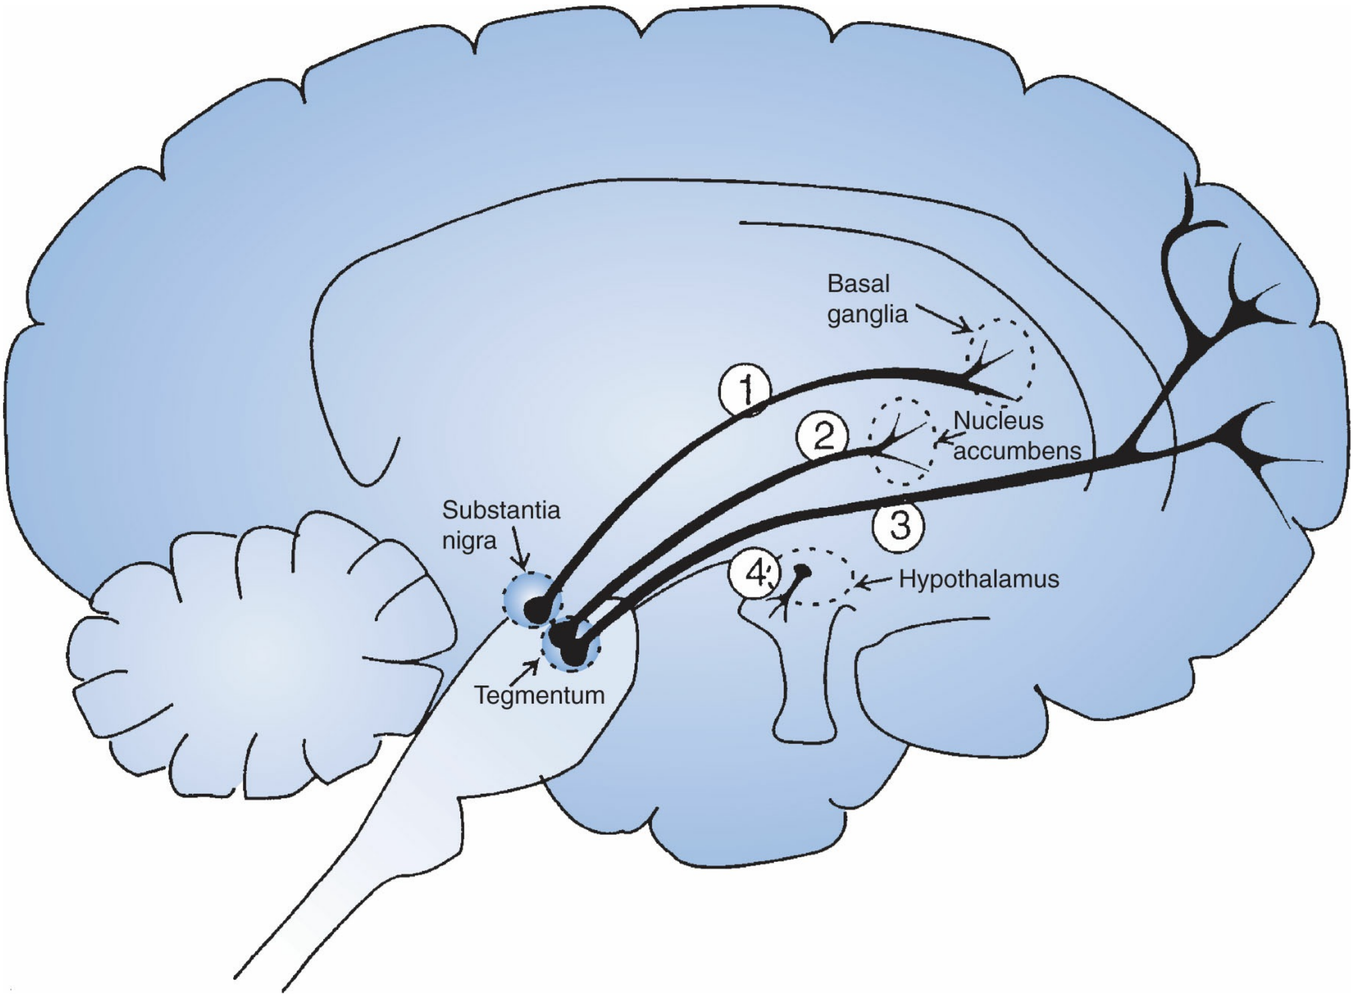

Figure 85-1 Four dopamine pathways in the brain. The neuroanatomy of dopamine neuronal pathways in the brain can explain both the therapeutic effects and the side effects of the known antipsychotic agents. (1) The nigrostriatal pathway projects from the substantia nigra to the basal ganglia and is thought to control movements. (2) The mesolimbic pathway projects from the midbrain ventral tegmental area to the nucleus accumbens, a part of the limbic system of the brain thought to be involved in many behaviors, such as pleasurable sensations and the powerful euphoria of drugs of abuse, as well as delusions and hallucinations of psychosis. (3) A pathway related to the mesolimbic pathway is the mesocortical pathway. It also projects from the midbrain ventral tegmental area, but sends its axons to the limbic cortex, where it may have a role in mediating positive and negative psychotic

symptoms or cognitive side effects of neuroleptic antipsychotic medications. (4) The fourth dopamine pathway of interest is the one that controls prolactin secretion, called the tuberoinfundibular pathway. It projects from the hypothalamus to the anterior pituitary gland.

General Differentiating Characteristics of Antipsychotics

It is sometimes useful to conceptualize the different antipsychotic medications in terms of their action at different receptor subtypes or by potency (Table 85-4). The second-generation antipsychotics (SGAs) are more potent at blocking 5-HT_{2a} serotonergic receptors than they are at blocking D_2 receptors. The SGAs are generally less likely to cause drug-induced parkinsonism and tardive dyskinesia than first-generation medications, but some of these agents may be more prone to cause metabolic issues than the FGAs.[52] Low-potency antipsychotics are often given in hundreds of milligrams per day and tend to have greater antihistaminic, anticholinergic, and α-1 antagonist effects than their high-potency (roughly 1–20 mg daily) counterparts.

Typical Antipsychotics or First-Generation Antipsychotics

Low-potency phenothiazine antipsychotics include the prototype antipsychotic chlorpromazine as well as thioridazine and its metabolite mesoridazine. Low-potency typical antipsychotics are strong histamine-1 blockers and are associated with more weight gain than the high-potency ones. They also tend to be strong blockers of α-1, inducing orthostasis, and muscarinic receptors, which results in dry mouth, blurred vision, and constipation. Thioridazine is distinctive in that it can cause a retinopathy in doses over 800 mg daily. Moreover, it has received a black box warning as it can cause prolonged QT_c intervals that can be clinically significant, especially if a 2D6 P450 isoenzyme antagonist (which increases its serum levels) is also being used.[63] Use of thioridazine is restricted to treatment-resistant patients due to these proarrhythmic effects, and use in clinical practice is uncommon.

Table 85-4

Clinical Effects of Receptor Antagonism by Antipsychotics

Receptor (Subtype)	Clinical Effect of Antagonism
Dopamine (D_2)	Mesolimbic pathway (basal ganglia)—treatment of positive symptoms Mesocortical pathway (prefrontal cortex)—may worsen negative symptoms Nigrostriatal pathway (substantia nigra)—extrapyramidal symptoms (EPS) Tuberoinfundibular pathway (hypothalamus–anterior pituitary)—increased prolactin release
Serotonin (5-HT_{2a})	Treatment of negative symptoms; increased dopamine release in prefrontal

	cortex; may reduce mesolimbic dopamine release
Serotonin (5-HT$_{2c}$)	Implicated in antipsychotic-associated weight gain
Muscarinic (μ_1)	Anticholinergic side effects (dry mouth, constipation, urinary retention, blurred vision, hot/dry skin, memory impairment); sedation
Histamine (H_1)	Increased appetite, sedation
Alpha (α_1)	Orthostatic hypotension

Common middle-potency typical antipsychotics include molindone, loxapine, and perphenazine. Molindone is the only antipsychotic associated with weight loss.[53,54] Loxapine is regaining use due to its inhalation dose form, and perphenazine has had a resurgence in use of sorts due to it being the chosen typical antipsychotic in the CATIE-1 trial.[64] These agents tend to fall in between the high- and low-potency agents in terms of adverse effects.

The high-potency typical antipsychotics are very selective for D_2 receptor blockade, thus causing fewer adverse effects related to antihistaminic, anticholinergic, or α-1 receptor blocking effects. However, they are more likely to induce adverse extrapyramidal effects such as dystonia, drug-induced parkinsonism, and akathisia than the lower-potency typical agents. Their availability as long-lasting depot injections of haloperidol and fluphenazine and reduced rate of adverse metabolic effects encourage their continued use. Other, less often utilized high-potency agents include thiothixene and trifluoperazine (Table 85-5)**.**

Atypical or Second-Generation Antipsychotics

SGAs are agents that exert more effects on antagonism of 5-HT$_{2a}$ subreceptors than on D_2 receptors and cause dramatically less drug-induced extrapyramidal symptoms. The SGAs such as clozapine, quetiapine, and olanzapine are more likely to induce metabolic disorders, such as weight gain,[65] hypertriglyceridemia,[66–70] and possibly glucose dysregulation[71] than other antipsychotic medications. Atypical antipsychotics are thought by many to have greater efficacy in the treatment of negative and cognitive symptoms of schizophrenia and a reduced risk of tardive dyskinesia.[62]

Clozapine has a unique pharmacology which makes it the only agent found to be effective in treatment-resistant schizophrenia and suicidality in schizophrenia.[56,62] Clozapine is associated with a higher incidence of agranulocytosis and neutropenia relative to other antipsychotics which requires frequent serum monitoring. This agent will be discussed more in the section on treatment-resistant schizophrenia. Risperidone (Risperdal) is considered to be an atypical antipsychotic that is effective and less likely to cause extrapyramidal system adverse effects at doses less than 6 mg/day. Akathisia can be a problem especially in the elderly. Paliperidone (Invega), or 9-hydroxyl risperidone, is the active metabolite of risperidone and has shown itself to be as effective as the parent drug.[72] Paliperidone is a controlled-release OROS oral dosage form that utilizes osmotic pressure to deliver the medication in a controlled fashion. Patients should be counseled not to be alarmed if the insoluble outer tablet shell is found in their stool. The long-acting injectable dosage forms of paliperidone and its parent compound risperidone are discussed in the section regarding long-acting agents.

Olanzapine (Zyprexa) is an atypical antipsychotic that is very effective, but it can cause significant weight gain with related glucose dysregulation as well as increased serum triglycerides.[68,73] Doses may need to be adjusted in smokers due to the induction of the cytochrome p450 1A2 isoenzyme system by the polycyclic aromatic hydrocarbons (PAHs) in cigarette smoke.[74] Quetiapine (Seroquel) is a low-potency D_2 antagonist.[64] Due to its minimal risk of drug-induced movement disorders, it is often utilized in patients with psychosis in Parkinson disease prior to use of clozapine.[75] It is recommended that patients be counseled regarding diet and exercise prior to and during the use of these agents and clozapine. Ziprasidone (Geodon) should be administered with at least 500 calories to ensure sufficient absorption.[76] It causes little weight gain or dyslipidemia and has minimal anticholinergic or extrapyramidal adverse effects. Although there were initial warnings about cardiac conduction delays (prolonged QT interval), there have been sparse reports linking the medication to death due to this concern.[77–79] An electrocardiogram prior to and during treatment is advised.[80]

Table 85-5

First-Generation Antipsychotics (FGAs)[279–287]

Medication Name (Generic/Brand); Potency—Chlorpromazine Equivalents; Class	**Dosage Forms**	**Adult Dosing Schedules**	**Dose Adjustments**
Haloperidol (Haldol) High—2 Butyrophenone	Tablet: 0.5, 1, 2, 5, 10, 20 mg Oral solution: 2 mg/mL Injectable (immediate-release): 5 mg/mL Injectable (long-acting): 50, 100 mg/mL	Initial: 0.5–5 mg BID or TID (depending on symptom severity) Usual range: 5–40 mg	Renal: No specific recommendations Hepatic: No specific recommendations
Fluphenazine (Prolixin) High—2 Phenothiazine	Tablet: 1, 2.5, 5, 10 Oral Elixir: 2.5 mg/mL Oral Solution: 5 mg/mL Injectable (immediate-release): 2.5 mg/mL Injectable (long-acting): 25 mg/mL	Initial: 2.5–10 mg q6–8 hours Usual range: 1–40 mg/day	Renal: Use with caution (nondialyzable) Hepatic: Use with caution

Thiothixene (Navane) High—4 Thioxanthene	Capsule: 1, 2, 5, 10 mg	Initial: 6–10 mg daily (divided doses) Usual range: 5–60 mg/day	Renal: Use with caution (nondialyzable) Hepatic: Consider dose reduction
Trifluoperazine (Stelazine) High—5 Phenothiazine	Tablet: 1, 2, 5, 10 mg	Initial: 2–5 mg BID Usual range: 15–20 mg/day	Renal: Use with caution (nondialyzable) Hepatic: Consider dose reduction
Perphenazine (Trilafon) Mid—8–10 Phenothiazine	Tablet: 2, 4, 8, 16 mg	Initial: 4–8 mg TID Usual range: 8–64 mg/day	Renal: No specific recommendations Hepatic: Consider dose reduction
Loxapine (Loxitane) Mid—10 Dibenzoxazepine	Capsule: 5, 10, 25, 50 mg Inhalation powder: 10 mg	Initial: 10 mg BID Usual range: 20–250 mg/day (PO)	Renal: No specific recommendations Hepatic: No specific recommendations
Chlorpromazine (Thorazine) Low—100 Phenothiazine	Tablet: 10, 25, 50, 100, 200 mg Injection (immediate-release): 25 mg/mL	Initial: 100–200 mg/day in divided doses; increase 20–50 mg/day q3–4 days as indicated	Renal: No specific recommendations Hepatic: Consider dose reduction
Thioridazine (Mellaril) Low—100 Phenothiazine	Tablet: 10, 25, 50, 100 mg	Initial: 50–100 mg TID with gradual dose increases Usual range: 50–800 mg/day	Renal: Use with caution (nondialyzable) Hepatic: Consider dose reduction

Aripiprazole (Abilify) should be dosed in the morning as it may be activating in some patients due to its partial D$_2$ receptor agonism. Typical adverse effects include nausea, vomiting, and insomnia in the first weeks of treatment. It has a lower risk of weight gain, dyslipidemia, and QT delays, and can actually cause decreases in serum prolactin and triglycerides. In fact, it has been used as augmentation to remedy hyperprolactinemia induced by other antipsychotics.[81–83] It also seems to have a low risk of EPS. Although aripiprazole's unique differential effect on dopaminergic systems can be beneficial, dopamine-3 (D$_3$) partial agonism may induce an increase in risky, reward-based behaviors, such as gambling.[84,85] Brexpiprazole (Rexulti) is a recent addition to the antipsychotic armamentarium that showed superiority to placebo in both key clinical trials (at 4 mg daily) with pharmacologic and therapeutic similarities to aripiprazole.[86,87] It is a partial agonist at D$_2$ receptors and serotonin 5-HT$_{1a}$ and antagonist at 5-HT$_{2a}$ and noradrenergic α-1b and α-2c receptors.[88] It is metabolized by both 2D6 and 3A4 hepatic isoenzyme systems, and dose reductions are recommended if these systems are inhibited.[89] Cariprazine (Vraylar) is pharmacologically similar to aripiprazole and brexpiprazole in that it is an antagonist at the D$_2$ receptors and 5-HT$_{2A}$ receptors and a "partial" agonist at 5-HT$_{1A}$ receptors. However, it has about a 10-fold greater affinity for the D$_3$ receptor than the D$_2$ receptor.[90] It is unclear what differences will result from its stronger effects on D$_3$ receptors.[91–93]

Iloperidone (Fanapt) is less likely to cause drug-induced parkinsonism, akathisia, and hyperprolactinemia than the typical antipsychotics, but has a risk of moderate weight gain, orthostasis, and the potential to cause QT interval prolongation that can be of concern in some patients.[94,95] Asenapine (Saphris) needs to be administered sublingually for rapid and adequate absorption. It has an absolute bioavailability of 35% when taken sublingually and less than 2% when swallowed. The patient should be counseled not to eat or drink for 10 minutes after the sublingual administration. The most common adverse reactions (≥5% and at least twice the rate of placebo) are somnolence, dizziness, extrapyramidal symptoms other than akathisia, and weight gain.[96] Lurasidone (Latuda) is an effective agent with a low propensity to cause drug-induced parkinsonism, metabolic complications, or QT_c prolongation. It needs to be taken with food (about 350 calories or more) for adequate absorption. The most common adverse events associated with lurasidone treatment are nausea, vomiting, akathisia, dizziness, and sedation (Table 85-6).[97]

Mechanism of Drug Action

All antipsychotic medications have at least some D_2 antagonistic effects. These antipsychotic medications have been divided into two major classes depending on whether or not they substantially antagonize 5-HT_{2a} receptors as well as dopaminergic ones. Although activity in attenuating dopamine transmission in the mesolimbic pathway is seen as being beneficial in decreasing the severity of positive schizophrenic symptomatology, decreased activity of dopamine receptors in mesocortical pathways (sometimes due to antipsychotic medication) may relate to the severity of negative symptoms. Antagonism of 5-HT_2 receptors in the striatum by SGAs may balance decreased dopaminergic neurotransmission and decrease their relative propensity to cause tardive dyskinesia.[98]

Selection of an Antipsychotic

Antipsychotic choice is based upon a number of factors, many of which are patient specific. In making a selection, consider such patient factors as treatment history (if any), medical comorbidities and concurrent medications, patient preferences, and potential cost concerns. If the patient has a known history of being treated with antipsychotics, this can help guide current selection. Previous positive response to an antipsychotic is a good indicator of future response, just as previous lack of response would recommend against trying that agent in the future. History of adverse effects to particular agents is useful also. If a patient is known to have had an adverse event to a specific agent in the past that would preclude them from receiving this agent again (including a patient's stated preference for this reason), then this will help guide current medication selection. Additionally, if an adverse effect led to medication discontinuation or poor adherence in the past, an antipsychotic should be selected that has a minimal risk of causing that adverse effect in the future. If information about a patient is not available, particularly in newly diagnosed patients with no prior treatment, medication history for a first-degree relative with schizophrenia may be useful in selecting an agent for the patient in a similar manner.

One area of debate has been selecting between FGAs and SGAs. Studies comparing the two classes head-to-head have shown similar efficacy rates between them.[99,100] Where the older agents are more prone to cause movement disorders, such as extrapyramidal syndromes (EPSs), the newer agents are thought to be more prone to causing metabolic disturbances in patients. Although SGAs are widely considered first choice in clinical practice,[101] most treatment guidelines now consider either FGAs or SGAs (other than clozapine) as potential first-line choices for treatment, depending upon the patient factors described above.[102,103]

CASE 85-1, QUESTION 6: Which type of antipsychotic medication would you recommend for J.J. at this time? What factors would you use to select a treatment regimen for her?

As J.J. has never been treated with an antipsychotic before, most any type is potentially viable as a treatment. Atypical antipsychotics would most likely be preferable. Typical antipsychotics, while efficacious, might lead to significant extrapyramidal or other adverse effects that she might not tolerate well, possibly leading to nonadherence. Also, with chronic usage typical antipsychotics (FGAs) are more likely to cause tardive dyskinesia than SGAS. As she is young and fairly healthy, we would also want to select an atypical antipsychotic with minimal long-term risks of metabolic adverse effects, such as weight gain and glucose irregularities. Pharmacoeconomic considerations should also be taken into account, as some of the atypical antipsychotics are available generically and some are not.

CASE 85-1, QUESTION 7: What pharmacologic agents should be considered first to treat JJ considering her acute symptoms?

In light of J.J.'s acute psychotic symptoms and agitation, a combination of both antipsychotics and adjunctive agents should be considered at this time. Although antipsychotics are generally the mainstay of schizophrenia treatment, they may not reduce symptoms quickly enough. Benzodiazepines may also be useful, especially during periods of increased agitation. Use of adjunctive medications to treat any adverse effects, such as EPS, may also be needed. Depending upon J.J.'s compliance to oral medications or during any periods of increased agitation, intramuscular (IM) injections of medications, including antipsychotics, benzodiazepines, and side effect medications, may need to be utilized acutely.

EFFICACY

Although there are numerous studies demonstrating the efficacy of current antipsychotic medications in comparison with placebo and accepted treatment, more attention has been paid of late to effectiveness studies comparing currently available antipsychotics. These effectiveness trials are intended to show the comparative value of these agents in situations that are more comparable to routine clinical care by utilizing less stringent eligibility criteria, longer duration, prospective design, and large sample size.[104] Still, they are randomized double-blind trials using intent-to-treat analysis just as if they were efficacy studies. Interpreting these studies is a help in bridging the chasm between studies in ideal populations and routine clinical care.

One of the landmark effectiveness trials comparing antipsychotic agents is the National Institute of Mental Health (NIMH) funded Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) trial. The first phase of the CATIE trial compared the SGAs quetiapine (n = 329), ziprasidone (n = 183), risperidone (n = 333), and olanzapine (n = 330) with the middle-potency FGA perphenazine (n = 257). The main outcome variable was time to discontinuation of the antipsychotic for any cause. Overall, 74% of the patients discontinued treatment over the 18-month course of the study. This study showed significantly less medication discontinuation ($p < .001$) in olanzapine-treated patients (64%) than in those receiving quetiapine (82%) or risperidone (74%). After adjusting for multiple comparisons, the difference between olanzapine and ziprasidone or perphenazine did not reach significance. When analyzed separately, the discontinuation rates due to intolerability were substantially higher in the olanzapine-treated patients, but there was a significantly greater time to discontinuation with olanzapine compared to quetiapine, risperidone, and perphenazine. The lowered number of patients in the ziprasidone group reduced the power (and thus chance to find difference) for comparisons with this agent and the others. The 18-month duration of the study could not yield information on the long-term effects of these agents in causing tardive dyskinesia or metabolic disorders.[64]

Table 85-6

Second-Generation Antipsychotics (SGAs)[288–296]

Medication Name(Generic/Brand)	Dosage Forms	Adult Dosing Schedules	Dose Adjustments
Aripiprazole (Abilify)	Tablet: 2, 5, 10, 15, 20, 30 mg ODT: 10, 15 mg Injectable (short-acting): 9.75 mg/1.3 mL Injectable (long-acting):	Initial: 10–15 mg/day, titrate at 2 week intervals Usual range: 15–40 mg Max: 30 mg/day	Renal/Hepatic: No dose adjustment necessary

	300 mg/vial and 400 mg/vial Solution: 1 mg/mL		
Asenapine (Saphris)	Sublingual tablet: 5, 10 mg	Initial: 5 mg BID (no benefit demonstrated with higher doses)	Renal/Hepatic: No dose adjustments necessary; use not recommended in severe hepatic impairment
Brexpiprazole (Rexulti)	Tablet: 0.25, 0.5, 1, 2, 3, 4 mg	Initial: 1 mg days 1–4; 2 mg days 5–7; 4 mg day 8 Usual range: 4 mg daily	Renal: 3 mg max in CrCl < 60 mL/minute Hepatic: 3 mg max in Child-Pugh score ≥ 7
Cariprazine (Vraylar)	Capsule: 1.5, 3, 4.5, 6 mg	Initial: 1.5 mg day 1, inc. to 3 mg day 2, inc. in 1.5–3 mg increments as needed Usual range: 1.5–6 mg	Renal: Not recommended in CrCl <30 mL/minute Hepatic: Not recommended in severe impairment (Child-Pugh score 10–15)
Clozapine (Clozaril)	Tablet: 12.5, 25, 50, 100, 200 mg ODT: 12.5, 25, 100 mg	Initial: 12.5–25 mg/day, titrate by 25–50 mg/day to target of 300–450 mg/day Usual range: 350–600 mg Max: 900 mg/day	Renal/Hepatic: No specific recommendations
Iloperidone (Fanapt)	Tablet: 1, 2, 4, 6, 8, 10, 12 mg	Initial: 1 mg BID, increase by 2 mg/day to target dose of 12–24 mg/day Max: 24 mg/day	Renal: No adjustments necessary Hepatic: Use not recommended
Lurasidone (Latuda)	Tablet: 20, 40, 80, 120 mg	Initial: 40 mg daily taken with food Usual range: 40–160 mg/day Max: 160 mg/day	Renal: Initial dose of 20 mg/day and max of 80 mg/day in moderate–severe impairment Hepatic: Initial dose of 20 mg/day and max of 80 mg/day in moderate impairment and max of 40 mg in severe impairment
Olanzapine (Zyprexa)	Tablet: 2.5, 5, 7.5, 10, 15, 20 mg ODT: 5, 10, 15, 20 mg Injection (short-acting): 10mg/vial (5mg/ml after reconstitution) Injection (long-acting): 210, 300, 405 mg/vial	Initial: 2.5–10 mg/day Usual range: 20–40 mg/day Max: FDA recommended max is 20 mg/day	Renal: Initial dose of 5 mg/day should be considered Hepatic: Childs Pugh Class A and B, no adjustment necessary
Paliperidone (Invega)	Tablet (ER): 1.5, 3, 6, 9 mg Injectable (long-acting): 39, 78, 117, 156, 234 mg prefilled syringes	Initial: 6 mg/day; increases should not exceed 3 mg every 5 days Usual range: 9–12 mg Max: 12 mg/day	Renal: CrCl 50–79 mL/minute: initiate at 3 mg, max 6 mg/day CrCl 10–49 mL/minute: initiate at 1.5 mg, max 3 mg/day CrCl <10 ml/minute: use not recommended

			Hepatic: Child-Pugh Class A and B no adjustment required
Quetiapine (Seroquel)	Tablet (IR): 25, 50, 100, 200, 300, 400 mg Tablet (ER): 50, 150, 200, 300, 400 mg	Initial (IR): 25 mg BID; titrate in 25–50 mg increments, given 2–3 times daily, to a target range of 300–400 mg/day by day 4; further adjustments at 25–50 mg increments with at least 2 days between adjustments; usual range 300–750 mg/day Initial (ER): 300 mg/day; target 400–800 mg/day Max: 800 mg/day	Renal: No specific recommendations Hepatic: Initiate IR tablets at 25 mg/day and increase by 25–50 mg/day increments/day; initiate ER tablets at 50 mg/day and increase by 50 mg/day increments
Risperidone (Risperdal)	Tablet: 0.25, 0.5, 1, 2, 3, 4 mg ODT: 0.5, 1, 2, 3, 4 Solution: 1 mg/mL Injectable (long-acting): 12.5, 25, 37.5, 50 mg	Initial: 1–2 mg/day; usual 4–6 mg/day Usual range: 4–8 mg/day Max: 16 mg/day	Renal/Hepatic: Recommend initial dose of 0.5 mg BID; may increase dose 0.5 mg BID; increases above 1.5 mg BID should be completed over 1 week intervals
Ziprasidone (Geodon)	Capsule: 20, 40, 60, 80 mg Injectable (short-acting): 20 mg/mL	Initial: 20 mg BID with food; dose adjustments at ≥48 hour intervals Max: 80 mg BID	Renal: No adj. necessary in mild-mod. Impairment use IM with caution Hepatic: No adj. necessary in mild-mod. impairment

Patients who discontinued treatment were eligible for enrollment in phase two of the CATIE to receive a different antipsychotic if they dropped primarily for lack of tolerance or efficacy. Those primarily not responding in the earlier phase could instead enter in the phase two trial in which there was a clozapine treatment arm.[105] In the lack of tolerability arm, patients assigned to olanzapine (n = 68) or risperidone (n = 70) showed longer time to discontinuation rates than those receiving either quetiapine (n = 63) or ziprasidone (n = 135).[106] In the poor responder study arm, patients receiving clozapine (n = 45) showed a significantly lower ($p <.05$) time to discontinuation of treatment than those receiving either olanzapine (n = 17), quetiapine (n = 14), or risperidone (n = 14).[107] The third phase of the CATIE trial involved with the 270 patients who discontinued treatment in the earlier phases, who went on to receive either aripiprazole, clozapine, olanzapine, perphenazine, quetiapine, or risperidone. The lack of power made it difficult to show any differences in effectiveness between these agents, and in this open trial few patients received either perphenazine (n = 4) or fluphenazine decanoate (n = 9).[108] Of note, at each subsequent phase of CATIE, statistical power was reduced as compared to the original study due to subject attrition, thereby increasing type II error.

Another often cited study is the Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study (CUtLASS 1) in which 227 patients were randomized to receive either FGAs (n = 118) or to be treated with a SGA (n = 109). This pragmatic, nonindustry-funded study was powered only to compare the overall differences between FGA and SGA groups and not the individual antipsychotics themselves. The hypothesis that second-generation medications would have an advantage on any quality of life measures over first-generation medications was disproven.[109] The CUtLASS 2 study was similarly designed and compared clozapine to other SGAs in patients who did not respond sufficiently to two prior treatments. Patients on clozapine showed significant improvements on PANSS scores ($p < .01$) and felt they did much better ($p < .05$), and there was a trend for improvement ($p =.08$) on their quality of life as measured on the QLS.[109,110]

SGAs have also shown better response and remission rates than haloperidol in first-episode patients.[111] Meta-analyses and related techniques have been utilized to attempt to overcome limitations of low power in comparative antipsychotic efficacy trials. One meta-analysis looked at 150 double-blind RCTs in over 20,000 patients and found only amisulpride (not available in USA.), clozapine, olanzapine, and risperidone to be more effective than the FGAs. The SGAs showed fewer EPS and, with the notable exception of aripiprazole and ziprasidone, caused more weight gain than haloperidol. However, there were no significant differences in weight gain between the low-potency typical antipsychotics such as chlorpromazine and the second-generation agents.[112]

One controversial topic not clearly covered by effectiveness trials or meta-analysis is the use of combinations of antipsychotic medications.[113] Although combination use is a relatively common practice,[114] it is not recommended due to the paucity of evidence for its safety and efficacy[115,116]; in fact, combination antipsychotic therapy is often targeted by quality improvement programs.[117] Although there are situations (i.e., adding aripiprazole to a patient stabilized on risperidone to attenuate hyperprolactinemia) in which this use can be logical and beneficial,[28,113,118,119] there are other times when treatment-resistant patients should receive alternative approved effective pharmacotherapy with clozapine.[120]

DOSAGE FORMS

Antipsychotics are commercially available in a variety of dosage forms to allow for different treatment situations and settings. The most common forms consist of orally administered products such as tablets/capsules (both short-acting and long-acting forms), orally disintegrating tablets (ODTs), and oral liquid solutions/suspensions. Many antipsychotics are also available as injectables, some as short-acting IM forms and some as long-acting IM forms. Selection of an appropriate dose form can depend upon factors such as the severity of the patient's illness and risk of imminent harm to themselves or others, willingness or ability to take medications, and treatment setting.

Alternate Oral Dose Forms

Although most every antipsychotic is available as a traditional tablet or capsule, many are available in other oral dosage forms. In an effort to help with adherence, several antipsychotics are available as either oral liquids or ODTs. The SGAs such as aripiprazole, risperidone, and ziprasidone are available as oral liquids, which may be useful in patients who have a hard time swallowing traditional tablets (or won't swallow them) or to achieve more specific dosing, such as might be needed for pediatric or geriatric patients. ODTs are formulated to dissolve rapidly when placed on the tongue, needing only for the patient to swallow their own saliva to obtain medication absorption in the gut. This formulation is particularly useful in the inpatient setting when "cheeking" or nonadherence is suspected. Aripiprazole, clozapine, olanzapine, and risperidone are available as ODTs, and asenapine is available only as a sublingually dissolving tablet.

Short-Acting Injectables

The short-acting injectable formulations of antipsychotics are frequently utilized in the acute phase of illness. Patients presenting to psychiatric emergency services are often in crisis and can be at risk of harm to themselves or others. If nonpharmacologic de-escalation techniques fail and the patient refuses PO medication, short-acting IM injections are effective in rapidly targeting agitation related to psychosis. IM formulations avoid first-pass metabolism and thus are approximately 2 to 4 times as potent as oral formulations and reach peak concentrations within 30 to 60 minutes.[121] The FGAs such as haloperidol, fluphenazine, and chlorpromazine, as well as the SGAs such as olanzapine, ziprasidone, and aripiprazole are currently available in short-acting IM formulations.

There are currently no head-to-head trials comparing the efficacy of the available short-acting IM SGAs. However, their efficacy and safety were evaluated in a review of nine double-blind, randomized controlled trials. Data were extracted to compare olanzapine, ziprasidone, and aripiprazole to either placebo or active comparator (haloperidol or lorazepam) in order to calculate number needed to treat (NNT) and number needed to harm (NNH).[122] All three of the agents demonstrated superior efficacy to placebo, and the NNT was lowest for olanzapine and ziprasidone. Olanzapine 10 mg demonstrated superiority compared to haloperidol 7.5 mg (NNT = 5). A low-dose of aripiprazole 1 mg IM was shown to be less effective compared to haloperidol 7.5 mg IM (NNT = −5).[122] The available RCTs for Ziprasidone IM did not have an active comparator such as haloperidol or lorazepam

IM. The adverse effect profiles of the SGAs differed significantly in terms of NNH, though all three agents were associated with less EPS than haloperidol. Olanzapine was associated with a NNH of 50 for treatment-emergent hypotension.[122] This is in line with the manufacturer's recommendation to avoid concomitant administration with benzodiazepines. In one of the studies, aripiprazole demonstrated a NNH of 47 for akathisia when compared to placebo.[122] Data were not available to evaluate QT_c-prolonging effects of ziprasidone IM in terms of NNH. The manufacturer's guidance states ziprasidone IM is contraindicated in patients with a known history of QT prolongation, recent acute MI, or uncompensated heart failure. Caution should be taken when given with other medications known to increase the QT interval (i.e., Class Ia and III antiarrhythmics, thioridazine, chlorpromazine, moxifloxacin, etc.) and in patients with renal insufficiency due to the clearance of the cyclodextrin excipient through the kidney.[123]

Haloperidol short-acting IM is commonly the preferred agent on hospitals' acute agitation protocols because of its proven efficacy, low risk for orthostasis, and its ability to be administered with IM lorazepam, if necessary. The cost of haloperidol may also be advantageous versus the SGAs, but cost of IM anticholinergics (e.g., benztropine) must be taken into account with its higher risk of EPS. Overall, the short-acting IM dosage forms of the antipsychotic agents are a crucial piece of the treatment team's armamentarium and key to ensuring the safety of a patient with agitation related to acute psychosis (Table 85-7).

Table 85-7

Agents Used to Treat Acute Agitation[121,296–303]

Medication	Dosage Form	Dosing Schedule (As Needed)	Onset (minutes)	Max Dose/24 hours	Duration of Action (hours)
Lorazepam	PO (tablet), IM, IV	1–2 mg	60–90 (PO); 15 (IM)	10 mg	8–10
Typical Antipsychotics					
Haloperidol	PO (tablet), IM	5–10 mg every 0.5–2 hours	30–60 minutes	30 mg	Up to 24
Fluphenazine	PO (tablet), IM	1–2.5 mg every 6 hours (tablet); 1.25 mg every 6 hours (IM)	Not available	10 mg	6–8
Chlorpromazine	PO (tablet), IM	50 mg (IM); 100 mg (PO) every 1–4 hours	15–60	200 mg	Not available
Atypical Antipsychotics					
Olanzapine	PO (tablet), IM, ODT	5–10 mg every 2–4 hours	15–45	30 mg (IM), 20 mg (ODT)	24

Risperidone	PO (tablet, liquid), ODT	1–2 mg every 0.5–2 hours	60	4 mg	Not available
Ziprasidone	PO (tablet), IM	10–20 mg every 2–4 hours	30–60	40 mg	4
Aripiprazole	PO (tablet, liquid), IM, ODT	10–15 mg (tablet); 9.75 mg (IM) every 2 hours	1–3 hours	30 mg	Not available

IM, intramuscularly; IV, intravenously; ODT, oral disintegrating tablet; PO, orally.

Long-Acting Injectables

Long-acting injectable antipsychotics (LAIAs) are an option for patients with a history of medication nonadherence or in those patients that prefer LAIAs over once-daily oral antipsychotics. LAIAs allow the patient the option to decrease the frequency they need to make a decision to take medications. Oral antipsychotics require daily recommitment to be adherent versus biweekly, monthly, or quarterly with LAIAs. Lapses in adherence are also more apparent, and early interventions can be initiated if a patient fails to show for an injection appointment. Effectiveness and tolerability of the oral counterpart to an LAIA should be established prior conversion to the LAIA. Equivalent dosages of LAIAs do not pose greater risk for adverse effects than the oral antipsychotic with the exception of injection site pain.[124] LAIAs take months to reach steady state concentration; therefore, making dose adjustments to acutely target symptoms or manage adverse effects is inefficient.

A number of large-scale RCTs failed to demonstrate a significant benefit of LAIAs over oral antipsychotic medications in relapse prevention in schizophrenia.[125] A meta-analysis including a total of 5,176 patients enrolled in 21 RCTs of at least 6-month duration found LAIAs did not reduce relapse compared to oral antipsychotics.[126] This finding may be due in part to selection of a population of subjects with greater engagement in treatment, more insight, and high adherence to PO medications relative to the real-world patient population. Increased clinician contact, implicit or explicit efforts to monitor adherence, and free study medication also reduce the ability of RCTs to reflect relapse rates in more unstable patients who are often prescribed LAIAs. A 2-year, double-blind RCT, conducted by Rosenheck and colleagues, enrolled 369 patients with schizophrenia who were at risk of psychiatric hospitalization.[127] The patients were assigned to LAI risperidone or PO antipsychotic of clinician’s choice. No significant differences in psychiatric hospitalization rates, symptoms of psychosis, or measures of social functioning were found between groups. Mirror-image studies, which compare periods of treatment with oral antipsychotics and LAIAs in the same patient, have been proposed as a better method to capture the real-world effectiveness of LAIAs. A systematic review and meta-analysis examined 25 mirror-image studies of 5,940 patients with schizophrenia greater than 12 months (greater than 6 months each of oral and LAIA treatment). LAIAs were superior to oral antipsychotics in preventing hospitalization (16 studies, RR = 0.43; 95% CI, 0.35–0.53; $p < .001$) as well as decreasing number of hospitalizations (15 studies, RR = 0.38; 95% CI, 0.28–0.51; $p < .001$). These results should be interpreted with caution because mirror-image studies can have intrinsic expectation bias and return to a stable status may reflect the natural course of illness.[125]

Patients with recent-onset schizophrenia have inherently less understanding of the importance of treatment and adherence and may benefit from treatment with LAIAs. One RCT of LAI risperidone versus oral risperidone in 86 patients with recent-onset schizophrenia demonstrated lower rates of relapse in the LAI risperidone group (5% vs. 33%).[128] Another prospective, open-label RCT randomized patients with first-episode schizophrenia, schizophreniform, or schizoaffective disorder in a 2:1 ratio to recommendation of switch to LAI risperidone (n = 26) or continuation of oral antipsychotic (n = 11). Patients were followed for up to 104 weeks, and an initial trend towards greater adherence was seen at 12 weeks ($p = 0.058$) for patients accepting LAI risperidone. However, no significant difference was seen in time to initial nonadherence during overall study duration.[129]

Two high-potency FGAs, fluphenazine and haloperidol, are available as decanoate ester long-acting injectable (LAI) formulations. Conversion to the LAI formulation of haloperidol can be achieved either by administering 10 times the oral dose the patient is stabilized on or by administering 20 times the oral dose for a loading dose regimen.[130] The loading dose regimen more rapidly achieves therapeutic serum levels of haloperidol and allows for earlier discontinuation of oral medication.[124,130] The standard conversion requires oral overlap with the current dose of oral haloperidol for at least one month prior to being gradually tapered.[124] Fluphenazine decanoate is released faster than the haloperidol decanoate and achieves Tmax in approximately 24 hours. It is recommended that the oral medication be decreased by 50% upon administration of the first injection and discontinued after the second injection.[124,131] There are not enough data to support a loading dose regimen for fluphenazine decanoate. The standard oral to LAI conversion is 1.25 times the oral dose administered every 2 to 4 weeks.[131] A double-blind study reported no difference in relapse, symptoms, or adverse effects between groups stabilized on every 2-week versus every 6-week injection intervals.[132] These results suggest dosing intervals longer than the usual 2 to 4 weeks may be an option to reduce antipsychotic exposure without risk of relapse. Both decanoate ester formulations require utilizing the "Z-track technique" for administration. This prevents loss of medication, abscess formation, or subcutaneous lumps. However, it is more painful than standard injections.

SGAs currently available in LAI formulations are aripiprazole (Abilify Maintena and Aristada), risperidone (Risperdal Consta), paliperidone (Invega Sustenna and Invega Trinza), and olanzapine (Zyprexa Relprevv). Aripiprazole monohydrate

(Abilify Maintena) requires a 14-day oral overlap and is dosed monthly. Aripiprazole lauroxil (Aristada), a prodrug of aripiprazole, requires a 21-day oral overlap, but can be dosed every 4 weeks or every 6 weeks at the 882-mg dosage.[132] The normal starting dose of aripiprazole monohydrate for most patients will be 400 mg IM monthly. However, patients with renal impairment or concomitant administration with strong CYP3A4 and 2D6 inhibitors or inducers for greater than 14 days require dose adjustments which are detailed in Table 85-8. Dosing of aripiprazole lauroxil is converted from the oral dose requirement of each individual (i.e., 10-mg oral aripiprazole equates to 441-mg injection).

LAI risperidone is administered every 2 weeks and requires an oral overlap of 3 weeks due to delayed release of risperidone from suspension in copolymer microspheres. Less than 1% of the risperidone is released within the first 3 weeks postinjection. Paliperidone palmitate (Invega Sustenna) is dosed monthly and does not require oral overlap with the recommended loading regimen. In patients without renal impairment, the initial loading regimen consists of a 234-mg deltoid injection on day 1 followed by a 156-mg deltoid injection on day 8. Paliperidone palmitate should be avoided in severe renal impairment (CrCl <50 mL/minute). Paliperidone palmitate is also available in a formulation administered every three months (Invega Trinza) for patients stabilized on the monthly formulation for a minimum of 4 months. The dose of the 3-month formulation is 3.5-fold higher than the last dose of the monthly formulation. However, there is minimal difference in injection volume between the two formulations (1.5 mL for Invega Sustenna 234 mg vs. 2.625 mL for Invega Trinza 819 mg).

LAI olanzapine (Zyprexa Relprevv) has an associated risk evaluation and mitigation strategy (REMS) due to the risk of postinjection delirium/sedation syndrome (PDSS). PDSS results from supratherapeutic levels of olanzapine caused by accidental intravascular placement of the injection and rapid dissolution of olanzapine pamoate. Symptoms mimic olanzapine overdose and can include sedation, coma, and delirium. The administering facility must have available access to emergency response services and monitor the patient for at least 3 hours postinjection for signs and symptoms of PDSS. The risk of PDSS is 0.2% per injection, and history of prior tolerability does not translate to a lower risk of PDSS for future injections. LAI olanzapine distribution is restricted to the Zyprexa Relprevv Patient Care Program that requires the prescriber, facility, patient, and pharmacy be enrolled prior to releasing the injection. The high administrative burden placed on the facility and patient to coordinate the postinjection monitoring limits its use in clinical practice.

Table 85-8

Long-Acting Injectable Antipsychotics (LAIAs)[304–311]

PHARMACOKINETICS AND DRUG INTERACTIONS

Pharmacokinetics and potential for drug–drug interactions are necessary considerations for the safe and effective dosing of antipsychotic medications. One key point to keep in mind is the difference between the time to therapeutic effect and time to steady state plasma concentration. Response of positive symptoms of schizophrenia can be seen within days of treatment initiation. However, it may take 4 to 7 days, or longer dependent on the half-life of the antipsychotic, to achieve steady state plasma concentrations. The half-life of an antipsychotic may also be misleading in determining dosing frequency. Most antipsychotics should be dosed once daily, with the exception of asenapine and ziprasidone due to issues with absorption. Ability to dose these agents once daily is in part due to higher concentration and longer receptor occupancy in the CNS as well as longer duration of pharmacologic effect than is reflected by the serum concentration.[134] During initial titration, split day dosing is appropriate when targeting acute agitation or as the patient develops tolerance to peak concentration-dependent adverse effects (i.e., sedation and orthostatic hypotension). Once the patient can safely tolerate the medication, the dose can be consolidated to bedtime to help reduce pill burden and increase patient adherence.[135]

Antipsychotic drug interactions can be mediated through direct pharmacokinetic (PK) interactions or by additive pharmacodynamic (PD) effects. PK interactions usually involve phase I oxidative metabolism through the cytochrome P450 (CYP) system; however, interactions can occasionally involve phase II metabolism (e.g., glucuronidation). Many antipsychotics undergo metabolism through CYP1A2, 2D6, and 3A4 hepatic isoenzymes (see Table 85-9). The inhibition or induction of these CYP enzymes can result in clinically relevant changes in antipsychotic serum levels. For example, inhibition of CYP1A2 by the antidepressant fluvoxamine can cause a significant elevation in clozapine serum level and place the patient at risk for serious adverse effects, such as seizures. The reverse would be true for CYP1A2 induction. To use the same example, if a patient were to begin taking a CYP1A2 inducer, such as carbamazepine or phenytoin, the clozapine serum level would drop and place the patient at risk for recurrence of psychotic symptoms. A common CYP1A2 inducer that deserves special mention is cigarette smoke and the polyaromatic hydrocarbons (PAHs) contained within that smoke. PAHs, not nicotine, are responsible for the induction; therefore, it is important to note when an inpatient is stabilized on an agent metabolized by CYP1A2 (e.g., clozapine, olanzapine, asenapine) the serum level can drop by up to 50% if they resume smoking upon discharge. Many antidepressants and mood stabilizers also have potent effects on CYP metabolism, so caution should be taken when adding them to an antipsychotic regimen.[136,137] PD interactions occur when an additional agent is added to a patient's regimen that enhances an effect of the antipsychotic activity at the receptor site without directly affecting the serum level of the antipsychotic. For example, adding the potent anticholinergic agent benztropine to an SGA with anticholinergic properties, such as olanzapine or clozapine, will compound anticholinergic adverse effects such as constipation.

Table 85-9

Pharmacokinetic Comparisons of Antipsychotics

Antipsychotic Agent	Mean Half-Life (hours)	Major Metabolic Pathway
First-Generation Antipsychotics (FGAs)		
Chlorpromazine	24	CYP 2D6
Fluphenazine	14–16	CYP 2D6
Haloperidol	18	CYP 2D6, CYP 3A4
Loxapine	6–8	None (minor—CYP 1A2, CYP 2D6, & CYP 3A4)
Perphenazine	9–12	CYP 2D6
Trifluoperazine	3–12	CYP 1A2
Thioridazine	5–27	CYP 2D6
Thiothixene	34	CYP 1A2
Second-Generation Antipsychotics (SGAs)		
Aripiprazole	75–94	CYP 2D6, CYP 3A4
Asenapine	24	UGT1A4, CYP 1A2
Brexpiprazole	86–91	CYP 2D6, CYP 3A4
Cariprazine	48–336	CYP 3A4
Clozapine	8–12	CYP 1A2, CYP 3A4
Iloperidone	18–33	CYP 2D6, CYP 3A4
Lurasidone	18	CYP 3A4
Olanzapine	21–54	CYP 1A2, CYP 2D6
Paliperidone	23	Limited CYP 2D6, CYP 3A4
Quetiapine	7	CYP 3A4
Risperidone	3–20	CYP 2D6
Ziprasidone	7	Aldehyde Oxidase, CYP 1A2, CYP 3A4

PHARMACOECONOMIC CONSIDERATIONS

When the SGAs were first introduced in the 1990s, there was great concern over their higher cost compared to the older antipsychotics. As the FGAs were all available in cheaper generic forms, the newly marketed SGAs were still under patent protection and therefore anywhere from 10 to 100 times higher the cost than their older counterparts.[138] From 1997 to 2007, the amount spent on outpatient antipsychotic prescriptions in the US (not including the Veterans Affairs system) increased from $1.7 billion/year to $7.4 billion/year.[139] This represents a large percentage of overall US mental health expenses over this time period. As the SGAs have slowly become available in generic forms, the concern about their higher costs has decreased slightly, but cost differences still remain.

Although actual medication cost is commonly scrutinized when examining schizophrenia treatment, it needs to be balanced against other costs associated with the illness. Factors such as hospitalizations rates, outpatient service utilizations, and patient functionality also need to be considered. One study examining the outcomes of formulary restrictions of SGAs in over 100,000 Medicaid patients with schizophrenia found that from 2001 to 2008 these restrictions increased hospitalization rates by 13%, inpatient costs by 23%, and total Medicaid expenditures by 16%, while only reducing medication expenses by 4%.[140] In selecting an antipsychotic, medication costs should be considered, especially in light of the costs to overall public health, along with other factors mentioned previously such as efficacy and adverse effect profile.

ADVERSE DRUG REACTIONS

One of the main factors in selecting an antipsychotic includes the adverse effect profile of the agents being considered. Although many of these adverse effects are common across most, if not all, antipsychotics, the incidence of these effects can vary greatly. The common, class-wide adverse effects seen with these agents include EPS, anticholinergic effects, cardiovascular effects, metabolic effects (including hyperprolactinemia), and others.

As in treating any illness, a careful balance must be maintained between efficacy and tolerability. When an adverse effect is discovered in a patient, evaluation of the benefit-to-risk ratio of the medication should take place. Medication factors such as the degree of benefit to the patient, the severity and frequency of the adverse effect, and level of discomfort or distress to the patient should all be considered. In any situation, the patient should be included in any decision regarding adverse effect management. Unresolved adverse effects that significantly bother a patient can lead to nonadherence and potential treatment failure.

If an adverse effect is determined to be fairly mild and cause minimal patient distress, then it may not require any intervention beyond close monitoring to ensure it does not worsen over time. Many adverse effects may be little more than a slight annoyance and can be approached like this. As an adverse effect becomes more severe or distressing to a patient, it may require more direct intervention. A reduction in antipsychotic dose may be needed or addition of a secondary medication to treat a particular adverse effect (described below) may be required. If truly warranted, the antipsychotic may need to be changed to another agent where the likelihood of the adverse effect might be lower. One potential factor to consider is the risk of decompensation when changing antipsychotics. Antipsychotics share similar pharmacologic effects and have similar efficacy rates, but not all antipsychotics may be effective for a given patient.

When determined that a change in antipsychotics is warranted, either due to adverse effects, poor efficacy, or both, there are several methods that can be employed for switching. In instances where the change needs to be abrupt, perhaps due to a serious or life-threatening adverse effect, an immediate discontinuation of the old agent and initiation of the new agent should be considered. When more time can be given to the change of agents, a cross-titration from one agent to the other can be performed. In these instances, either the new agent can be increased over time as the old agent is simultaneously reduced, or the new agent initiated at a therapeutic dose followed by a downward taper of the old agent over time. The rates of these medication increases and decreases are determined by the clinical presentation and concerns for patient safety (Table 85-10).

Extrapyramidal Adverse Effects and Tardive Syndromes

The blocking of D_2 receptors in the striatum by antipsychotics can also cause acute adverse reactions such as dystonias (involuntary contractions of skeletal muscles) and drug-induced parkinsonism (pseudoparkinsonism). Restoring the balance between acetylcholine and dopamine in the striatum can reduce EPS, which is why low-potency FGAs with appreciable anticholinergic activity (i.e., chlorpromazine and thioridazine) can be less problematic than high potency in this regard. This can also be done using anticholinergics such as benztropine or trihexyphenidyl, by using amantadine, by lowering the dose of the antipsychotic, or by using an SGA instead. However, some evidence suggests that changing patients to an SGA will not always lead to the improvement in these movement disorders to the degree expected.[141]

Dystonia

Acute dystonias are uncomfortable, sustained muscle contractions which can occur as torticollis (involving the neck), the trunk, the tongue, or as an oculogyric crisis (where the patient’s eyes appear to roll up in the head). Oculogyric crisis and dystonias tend to present in the first few days of treatment. Symptoms are treated using anticholinergic medications via IM administration for rapid efficacy (i.e., benztropine 2 mg IM stat). Scheduled oral administration of the chosen anticholinergic agent is continued after acute symptom resolution. However, this rapid treatment often does not help the attitude of affected patients towards their caregivers when clinicians are trying to develop a therapeutic alliance with a patient who may already be prone to suspicion or paranoia.[142]

Parkinsonism

Drug-induced parkinsonism is the most common and reversible of adverse movement effects. It consists of rigidity, masked face, slowed gait, and tremor. These symptoms are short lived and easily treated. These occur most often in the first 3 months of treatment. Drug-induced parkinsonism is a separate entity from idiopathic Parkinson disease, which is a distinct illness on its own.

The high-potency FGAs are more likely to induce drug-induced parkinsonism than the low-potency agents. Increased dosages of FGAs in higher-risk patients (i.e., medication naïve, female, advanced age) increase this risk. SGAs are on the whole less likely to induce this syndrome. Clozapine and quetiapine are the least likely to induce drug-induced parkinsonism and often can be used without worsening the underlying movement disorder in patients with idiopathic Parkinson disease.[143–145] However, although clozapine has been robustly effective in these patients, reports with quetiapine are conflicting.[75]

Strategies for reducing or eliminating antipsychotic-induced parkinsonism include lowering the dose of antipsychotic, switching to an atypical antipsychotic (with the lowest risk choices being quetiapine or clozapine), or treating the patient with antiparkinsonian medication. The antiparkinsonian medications often used are anticholinergic agents such as benztropine (Cogentin; given from 0.5 mg BID to 2 mg TID), trihexyphenidyl (Artane), biperiden (Akineton), diphenhydramine, or the novel agent amantadine (Symmetrel; given from 100 to 400 mg daily in divided dosages). The anticholinergic agents add to adverse effect and pill burden, and continuation is often not necessary after 3 months. Amantadine causes less of these problems and works by an alternate mechanism of action; it is not as effective as the anticholinergics in many patients though.[142] Anticholinergic adverse effects are discussed in greater detail in the “Anticholinergic Adverse Effects” section.

Table 85-10

Relative Incidence of Antipsychotic Adverse Effects

	Sedation	EPS	Anticholinergic	Orthostasis	Weight Gain
Typical—Low Potency					
Chlorpromazine	+++	++	++	+++	
Thioridazine	+++	+	+++	+++	
Typical—Mid-Potency					
Loxapine	+	++	+	+	
Perphenazine	++	++	+	+	
Typical—High Potency					
Fluphenazine	+	++++	+	+	
Haloperidol	+	++++	+	+	
Thiothixene	+	+++	+	+	
Trifluoperazine	+	+++	+	+	
Atypicals					
Aripiprazole	+	+	0 to +	+	+
Asenapine	++	+	0 to +	++	+

Clozapine	+++	0	+++	+++	++++
Iloperidone	++	+	+	++	+
Lurasidone	+	+++	0	+	++
Olanzapine	++	+	++	++	++++
Paliperidone	+	+	0 to +	+	+
Quetiapine	++	0	0 to +	++	+++
Risperidone	+	++	0 to +	++	+++
Ziprasidone	++	++	+	++	+

0, no effect; +, low; ++, moderate; +++, high; ++++, very high; EPS, extrapyramidal side effects.

Akathisia

Akathisia can present alone or in combination with drug-induced parkinsonism, or tardive dyskinesia.[146,147] It presents as an inability to remain still combined with an intense feeling of internal restlessness that can make the patient appear quite agitated.[148] In the unfortunate event akathisia is incorrectly interpreted as agitation, increased or "as needed" antipsychotic doses to target agitation will worsen the syndrome. Akathisia is best treated by a small reduction in antipsychotic dosage, addition of low dosage β-adrenergic blockers (i.e., propranolol 10 mg bid or tid), or addition of anticholinergic agents (especially if drug-induced parkinsonism is also present). Benzodiazepines can also be used in patients not responsive to the aforementioned strategies (Table 85-11).

CASE 85-1, QUESTION 8: J.J. is eventually stabilized on brexpiprazole 2 mg daily while hospitalized. During the admission, the staff notices that her psychotic symptoms have decreased but that her agitation has slowly increased over time. She is constantly pacing around on the unit, and when she does sit down she is always fidgety and unable to sit still. She says she feels uncomfortable most of the time. The unit staff have had to continue to give her lorazepam 1 mg several times a day for this agitation. What form of an EPS might J.J. be experiencing at this time? What information in her presentation supports this finding?

J.J. is most likely experiencing akathisia. As her symptoms did decrease when brexpiprazole was initiated, it is unlikely that it is agitation due to her schizophrenia that is causing the restlessness. Antipsychotics, even those that are D_2 partial agonists such as brexpiprazole, are known to cause akathisia as an adverse effect. Her symptoms also appear to be akathisia: constant pacing/movement, always fidgety, and feeling of inner restlessness. Although lorazepam would be expected to treat agitation, it is also a potential treatment for akathisia as well.

CASE 85-1, QUESTION 9: What would be the appropriate treatment for J.J.'s akathisia?

Table 85-11

Agents to Treat Antipsychotic-Induced Parkinsonism and Akathisia

Medication	Equivalent Dose (mg)	Dose/Day (mg/day)
Anticholinergic		
Benztropine (Cogentin)[a]	0.5	1–8
Biperiden (Akineton)[a]	0.5	2–8
Diphenhydramine (Benadryl)[a]	25	50–250
Procyclidine (Kemadrin)	1.5	10–20
Trihexyphenidyl (Artane)	1	2–15
Dopaminergic		
Amantadine	—	100–300
GABAminergic		
Diazepam (Valium)	10	5–40
Clonazepam (Klonopin)	2	1–3
Lorazepam (Ativan)[a]	2	1–3
Noradrenergic Blockers		
Propranolol (Inderal)	—	20–60 (max = 120)

[a] Oral dose or intramuscular (IM) injection can be used.

Adapted from Facts & Comparisons eAnswers. http://online.factsandcomparisons.com/MonoDisp.aspx?monoID=fandc-hcp10202. Accessed May 15, 2016, with permission.

First and foremost, it should be determined whether J.J. can be stabilized on a lower dose of her medication. Often a reduction in antipsychotic dose will resolve any EPS symptoms. If this is not possible and J.J. would destabilize as a result, then an additional medication will be needed to manage the problem. Although lorazepam would serve this purpose, the concerns about chronic daily administration of benzodiazepines must be considered. As J.J. may have akathisia with brexpiprazole as long as she is on the medication, she could require treatment for akathisia this entire time. Another option for treating this problem would be propranolol, the nonselective β-blocker. Propranolol has been found to be helpful in alleviating akathisia in low, subcardiac doses such as 10 to 20 mg twice daily. If this treatment is selected, then her blood pressure and heart rate should be monitored accordingly.

CASE 85-1, QUESTION 10: When arranging her discharge, the pharmacy that is called for her prescriptions informs you that her insurance plan will not pay for brexpiprazole. What medication would be appropriate to switch JJ to at this time?

Ideally, we would keep J.J. on the medication that stabilized her during her hospitalization. It might be possible to contact her insurance to obtain a prior authorization for this medication. If that cannot be done, then they should be asked whether aripiprazole is available for use with J.J. Aripiprazole is also a D_2 partial agonist, like brexpiprazole, so theoretically it should work in a similar manner as brexpiprazole. If her insurance will not pay for aripiprazole, then another atypical antipsychotic with a similar adverse effect profile should be considered. As brexpiprazole has lower rates of EPS and metabolic adverse effects, an agent such as ziprasidone might be considered as it has similar rates of EPS and metabolic effects but is available as a generic medication.

CASE 85-1, QUESTION 11: JJ has been stabilized on ziprasidone 40 mg twice daily with meals while in the hospital. When should her target symptoms start to respond to the medication? What else can be done to help improve JJ's prognosis once she is discharged?

Although J.J.'s symptoms should start to decrease within a few days of starting the medication, it may take a week or longer to see significant improvement. At this point she may be stable enough for discharge from the hospital, but still show some functional deficits. It may take several more weeks, possibly months, for her to return to her baseline prior to her symptoms starting, and she may never fully reach this point. The utilization of nonpharmacologic methods, including individual and group therapy modalities, could also help J.J.'s continued improvement and stabilization. Education for both her and her family could also be of benefit to her.

CASE 85-1, QUESTION 12: JJ returns home to her family, taking a leave from college for the remainder of the semester. She returns to school the following semester to resume classes, but notices she has a hard time focusing in class, which she attributes to the ziprasidone. As she has not had any psychotic symptoms since being released from the hospital approximately 5 months ago, she thinks she is cured and no longer needs to take the medication. She contacts her psychiatrist about stopping the medication. Should J.J. discontinue her medication at this time? What do practice guidelines state regarding J.J.'s treatment needs at this time?

J.J. should not stop her medication at this time. Although a medication adjustment might be needed, depending upon the nature and cause of her concentration, that is not a reason to stop the medication altogether. Most treatment guidelines recommend a minimum of 6 months, and preferably one year, of treatment after a psychotic episode. As she has only been symptom-free for 5 months, J.J.'s risk of relapse is very high without medication treatment.

CASE 85-1, QUESTION 13: Ultimately, J.J. decides to stop taking her ziprasidone and stops going to her psychiatrist appointments. In less than a month, she is brought to the ER by her parents as she has relapsed into another psychotic episode and admitted back into the hospital. Is J.J. a candidate for long-acting injectable antipsychotics (LAIAs) at this time?

J.J. is not a candidate for a LAIA currently as she has never tried an oral formulation of any of them to this point. Recommendations for use of a LAIA require at a minimum repeated dosages of the oral form of the medication to ensure a lack of an allergy to the med, or in some instances for the patient to be stable on an oral dose of the medication and the converted over to the LAIA form. However, she might benefit from the use of a LAIA if she truly intends to be nonadherent with oral forms of antipsychotics. As she has only shown nonadherence to one medication trial due to a potential misunderstanding of her illness and her treatment, she could benefit from education in these areas to improve her adherence. In addition, her family could be educated to help J.J. maintain her med adherence as well.

CASE 85-1, QUESTION 14: While on the inpatient unit for this most recent episode, JJ continues to remain nonadherent to oral medication. She eventually agrees to receive an LAIA, but after speaking with her insurance the only atypical antipsychotic LAIA they will pay for is risperidone LAIA. Is this an appropriate agent for JJ, and why or why not?

Assuming that J.J. has been administered oral risperidone in the past which ensures a lack of an allergy to the medication, it still would not be an appropriate option at this time. Due to the unique pharmacokinetic parameters of risperidone LAIA, it requires 3 weeks of overlap of oral medication (risperidone or otherwise) as the initial dose does not begin releasing medication until this time. Assuming J.J.'s nonadherence to oral medications will continue, this could lead to a poor outcome, especially if she is discharged from the hospital. J.J.'s insurance should be contacted to attempt to find an alternative atypical antipsychotic LAIA.

Tardive Dyskinesia

One of the more troubling potential adverse effects from chronic treatment with antipsychotics is the development of persistent choreoathetoid (sometimes described as snake-like) movements of the tongue, hands, feet, and in severe cases even the trunk of the patient.[149] Chronic blockade of striatal D_2 receptors by antipsychotics results in these receptors becoming supersensitive to available dopamine. Changes in interconnected neurotransmitter systems, such as GABAergic or muscarinic,[150] can result in dyskinesias that can often appear on withdrawal of antipsychotics, upon lowering of the dosage, or when a patient is changed to clozapine or quetiapine treatment from another antipsychotic. If these withdrawal dyskinesias persist, then the condition of persistent or tardive dyskinesia can result. Tardive dyskinesia can also present without any change in medication dose after many years of treatment. FGAs are considered to have a much greater risk (5% yearly incidence in long-term use in adults) of causing tardive dyskinesia than the SGAs, but reported incidences vary appreciably between studies.[151] Risk of developing tardive dyskinesia increases with cumulative lifetime dosage and duration of antipsychotic treatment, increased age, comorbid diabetes mellitus, traumatic brain injury, having an affective disorder, anticholinergic medication use, a history of drug-induced parkinsonism, and female gender.[152–155] Although the incidence rate for patients treated with typical antipsychotics is more substantial,[151] the atypical antipsychotics also carry this risk albeit at a lower but still not negligible rate.[156]

Although all dyskinetic movements seen on withdrawal of antipsychotic medication are not necessarily persistent or tardive dyskinesia, there are those cases of patients who do retain the potentially stigmatizing movements long after antipsychotic medications are tapered or changed. When this occurs, it is often very difficult to remediate these movements. Medication changes which decrease the effects of dopamine on striatal receptors tend to cause immediate improvement followed by long-term worsening of dyskinetic symptoms. Few double-blind studies show any benefit of augmenting with various agents, and agents which often have shown promise in early case reports and open studies (i.e., diazepam, donepezil, branched chain amino acids) often do not bear up to the scrutiny of a double-blind trial.[157–159] Even accepted strategies such as lowering antipsychotic dosages (or stopping them when possible) or changing to less offending second-generation agents such as clozapine or quetiapine do not always yield the desired outcome. Some limited evidence suggests that clonazepam and ginkgo biloba may prove helpful.[159] However, a better course of strategy appears to do what we can to prevent the occurrence of tardive dyskinesia by strategies such as keeping antipsychotic dosages as low as possible and using medications that are less likely to induce this syndrome,[150,151,160] and incorporating close monitoring for development of symptoms utilizing the Abnormal Involuntary Movement Scale (AIMS) examination. However, we do have the option to tailor our medication choice to the vulnerability of the patient. As the severity and prevalence of tardive dyskinesia is apparently on the decline,[150] there may be cause to be optimistic.

Anticholinergic

The low-potency FGAs and certain SGAs, particularly olanzapine and clozapine, are potent muscarinic receptor antagonists. The resultant anticholinergic effects can range from bothersome to potentially life-threatening. These effects include dry mouth, blurred vision, mydriasis, tachycardia, urinary retention, constipation, paralytic ileus, confusion, and delirium. Something that may appear merely bothersome, like dry mouth, can have more serious consequences if not addressed. Dry mouth can lead to dental caries or weight gain if thirst is quenched with sugary beverages. Additional sugar, in the form of gum or liquids, can also increase the risk of oral fungal infections. Patients can utilize sugar free hard candies or gum, or saliva substitute products if anticholinergic medication dosage cannot be reduced.[161] In general, patients with schizophrenia should be encouraged to connect with regular dental services. Another often overlooked anticholinergic adverse effect is constipation. Patients may not draw the connection between constipation and a medication that they are taking for their mental health. Consistent monitoring of patient's bowel habits and recommendation of a proper bowel regimen (e.g., diet, physical activity, bulk-forming laxatives, stool softeners) can be the difference between a week of unaddressed bowel discomfort progressing to paralytic ileus and patient expiration due to bowel rupture or aspiration of gastric contents.[162]

The patient's overall anticholinergic burden is often increased by the addition of anticholinergic medications, such as benztropine, for EPS prophylaxis or treatment.

Indication for use of anticholinergic agents should be re-evaluated periodically during treatment and upon transitions in care. Failure to taper unnecessary anticholinergic medications can lead to decreased quality of life and preventable adverse effects.[163]

Cardiovascular Effects

Antipsychotic medications are thought to exert cardiovascular effects through direct antagonism of adrenergic and cholinergic receptors, as well as through indirect central autonomic effects and baroreceptor reflexes.[164] Three common antipsychotic-induced cardiovascular effects, orthostasis, tachycardia, and QT_c prolongation, are described below.

Orthostatic Hypotension

Orthostatic hypotension occurs in up to 40% of patients treated with antipsychotic medications.[164] It occurs frequently during the initial dose titration and disproportionately affects elderly patients. Orthostasis results from the blockade of vascular α_{1A}-adrenoceptors, which makes it difficult for patients to adapt to positional changes in blood pressure. Tolerance to orthostasis will usually develop within 2 to 3 weeks of antipsychotic initiation or dose increase. Antipsychotic agents with high affinity for α_{1A}-adrenoceptors relative to D_2 receptors (e.g., clozapine, risperidone) clinically display greater rates of orthostasis than agents with low α_{1A} affinity relative to D_2 affinity (i.e., haloperidol).[164] The risk for falls secondary to orthostasis can be mitigated by (1) slowing the rate of titration, (2) splitting the dose, and (3) counseling the patient to make slow transitions from prone and seated positions. Increasing fluid and salt intake and using support stockings are other nonpharmacologic interventions that may help alleviate orthostasis whereas the patient adapts to a change in dosage. More persistent orthostasis resulting from clozapine treatment can be managed with fludrocortisone or ephedrine if nonpharmacologic interventions are not clinically feasible.[165]

Tachycardia

Antipsychotic-associated tachycardia can occur as a direct effect of anticholinergic activity on vagal activity or as a compensatory mechanism related to orthostatic hypotension. Patients treated with clozapine tend to have a dose-related increase in heart rate of

---

20 to 25 beats/minute (bpm).[164] Dose reduction, slower titration, or addition of low-dose, preferably cardio-selective, β-blocker can be considered if tachycardia is

bothersome to the patient or symptomatic.[165,166]

Electrocardiographic Changes

Prolongation of the QT interval, or QT_c interval when corrected for heart rate, is a variable risk associated with all antipsychotics. QT_c interval prolongation increases the risk for torsades de pointes (TdP), a malignant polymorphic ventricular tachycardia that is associated with syncope and sudden cardiac death.[164] The potential mechanism for this effect is believed to be mediated through blockade of the rapidly activating delayed rectifying current (I_{Kr}) which conducts potassium out of the cardiomyocytes to cause cardiac repolarization.[164,167] However, there are insufficient data to establish the direct causal relationship between antipsychotic-induced QT_c prolongation and sudden cardiac death.[164,167]

The Pfizer 054 study, developed in consultation with the FDA, demonstrated QT_c prolongation as a class effect for SGAs.[168] This prospective, randomized, parallel-group study conducted by Harrigan and associates examined the effect of steady state peak plasma concentrations of haloperidol 15 mg/day (n = 27), thioridazine 300 mg/day (n = 30), ziprasidone 160 mg/day (n = 31), quetiapine 750 mg/day (n = 27), olanzapine 20 mg/day (n = 24), or risperidone 6 to 8 mg/day increased to 16 mg/day (n = 25/20) on the QT_c interval in the presence or absence of metabolic inhibitors in patients with stable psychotic disorders. No patients were observed to have a QT_c interval greater than 500 ms, and mean QT_c changes from baseline were similar for monotherapy and with concomitant administration of a metabolic inhibitor. The antipsychotics associated with the greatest change in mean baseline QT_c were thioridazine (30.1 ms) and ziprasidone (15.9 ms). Haloperidol, quetiapine, risperidone 6 to 8 mg/day, risperidone 16 mg/day, and olanzapine were associated with mean QT_c changes of 7.5, 5.7, 3.9, 3.6, and 1.7 ms, respectively.[169] To add context, the mean diurnal variation in QT_c is approximately 75 to 100 ms and this may vary further based on sleep, diet, obesity, electrolyte disturbances, endocrine dysfunction, gender, and age.[164,167] No cases of torsades de pointes were observed in the 4,571 ziprasidone-treated patients included in the Pfizer 054 study and the ziprasidone database.[168] One of the newer SGAs, iloperidone, has also demonstrated a dose-dependent and drug interaction-dependent risk of QT_c prolongation similar to that of ziprasidone in both short- and long-term randomized trials.[170]

In clinical practice, concomitant administration of QT_c-prolonging agents should be avoided. If coadministration is necessary in a patient with no underlying cardiac abnormalities or risk factors for TdP, the patient should be monitored closely. The interacting medication should be discontinued if the QT_c interval extends beyond 500 ms. Use of antipsychotics with higher risk of QT_c prolongation, chlorpromazine or ziprasidone, should be avoided in patients with underlying cardiac issues, electrolyte abnormalities (hypokalemia or hypomagnesaemia), congenital long-QT syndrome, or those comedicated with agents affecting cardiac function (particularly antiarrhythmics of class Ia—disopyramide, procainamide, quinidine—and class III—amiodarone, dofetilide, sotalol).

CASE 85-1, QUESTION 15: After intensive education about her illness and need for treatment, as well as enlisting the help of her parents in ensuring she will take her medications, JJ eventually agrees to take oral medications and is restabilized on risperidone 2 mg twice daily again. After discharge, her outpatient psychiatrist notes that JJ is still responding to internal stimuli, and confirms she is still having some auditory hallucinations. JJ's parents confirm she is taking her doses, so the dose is increased to 3 mg twice daily. Within a few weeks at her next appointment, JJ's parents inform her psychiatrist that she can barely move, and she "walks like an old lady" at times. The psychiatrist examines JJ and notes she has some mild stiffness in her extremities, a mild tremor in her hands, and when she walks her gait is abnormally short and almost shuffling in appearance. Her hallucinations have subsided however. What is the probable cause of JJ's abnormal neurologic findings at this time? What information in her presentation supports this finding?

J.J. is most likely suffering from drug-induced parkinsonism, a type of EPS. All the abnormal findings noted in J.J. at this time, stiffness, tremor, and shuffling gate, are characteristic findings for drug-induced parkinsonism. Although risperidone, as an atypical antipsychotic, is less likely to cause this problem compared to the older, conventional antipsychotics, it can still cause it. One risk factor of parkinsonism with risperidone is increasing the dose, which occurred in J.J. recently. Although she was fine on the lower dose, the increase in dose to 6 mg/day caused enough D_2 receptor blockade in the nigrostriatal pathway to induce this EPS type.

CASE 85-1, QUESTION 16: How can J.J.'s drug-induced parkinsonism be treated?

Ideally the first choice would be to decrease the dose of the offending agent. As J.J.'s dose of risperidone was just increased to 6 mg/day due to lingering symptoms, this is most likely not an option as it is highly likely those symptoms would return. A change in antipsychotics could also be considered, but it appears that other than the EPS, J.J. is currently stable on this medication and dose. The only other option would be to add another medication to treat her parkinsonism. Some options include the use of anticholinergic medications, such as benztropine, or the use of amantadine.

CASE 85-1, QUESTION 17: J.J.'s drug-induced parkinsonism resolves with the addition of benztropine 0.5 mg twice daily. Will JJ need to stay on this medication indefinitely?

J.J. should be maintained on benztropine for at least 3 months once her parkinsonism resolves. If there are no other changes in her clinical status or her medication treatment for her schizophrenia, then the use of benztropine should be re-examined at that time. If the medication is then removed and her parkinsonism does not return, then she should not need the medication any longer. Should the EPS return, however, then she may need continued anticholinergic treatment.

CASE 85-1, QUESTION 18: What are some other adverse effects that should be monitored for in JJ, both specific to risperidone and for antipsychotics in general?

Any patient receiving an antipsychotic should be monitored for all types of EPS, including parkinsonism. Other EPS types, such as dystonia and akathisia, should be watched for as well as the development of any tardive dyskinesia. Although the risk of these concerns is lower with an atypical antipsychotic, such as risperidone, it is still possible. J.J.'s weight and serum glucose and lipids should also be monitored regularly both during the initiation of antipsychotic treatment and periodically throughout. Risperidone also can cause drug-induced orthostasis, so she should be monitored for dizziness, especially upon standing.

Metabolic Effects

Hyperprolactinemia

Prolactin is a polypeptide hormone secreted by lactotroph cells in the anterior pituitary. Dopamine acts as an inhibitor of prolactin release in the tuberoinfundibular dopamine tract which projects

from the hypothalamus to the anterior pituitary. Blockade of D_2 receptors within this pathway leads to increased release of prolactin and potential effects on multiple organ systems and gene expression throughout the body. Agents that cause more potent D_2 blockade are associated with a greater risk of hyperprolactinemia.[171] A multiple-treatment meta-analysis by Leucht and associates stratified select antipsychotics based on their effect on the standardized mean difference in prolactin from baseline as follows: paliperidone (highest), risperidone, haloperidol, lurasidone, ziprasidone, iloperidone, chlorpromazine, olanzapine, asenapine, quetiapine, and aripiprazole (lowest/decreased prolactin).[172] Guidelines recommend baseline prolactin monitoring at the discretion of the clinician, screening for symptoms of excess prolactin at every visit for the first year of treatment and annually thereafter if symptoms are stable, and follow-up prolactin levels only if clinically indicated.[45,173,174] The upper limit of normal prolactin levels is 18 to 20 ng/mL in males and 24 ng/mL in females who are not pregnant or lactating.

Clinical sequelae from excess prolactin release include sexual dysfunction, gynecomastia, galactorrhea, amenorrhea, hypogonadism, and potential bone mineral density changes with long-term elevations. However, prolactin levels do not directly correlate with these adverse events and patients may remain asymptomatic. Considerations for treatment should only be addressed in actively symptomatic patients.[83,172] In symptomatic patients, dose reduction or switching to an agent with less potent D_2 blockade would be recommended first line. If these strategies fail to improve the symptoms or cannot be undertaken for clinical reasons, a dopamine agonist, such as bromocriptine, cabergoline, or amantadine, may be considered. However, the risk of potential exacerbation of psychosis must be weighed against potential benefit.[45,171,174,175] There is also growing evidence to support the use of adjunctive aripiprazole, a partial D_2 agonist, to improve hyperprolactinemia in patients who cannot be switched from a more potent agent.[81,83,176–178]

CASE 85-1, QUESTION 19: Over time J.J.'s dose of risperidone is increased to 4 mg twice a day due to lingering symptoms. At one of her follow-up appointments, JJ asks if it is safe to take the medication while she is pregnant. During the conversation, J.J. tells her psychiatrist that she is pregnant as she hasn't had her menstrual period in nearly 2 months, and her breasts have become larger and she has noticed she lactates periodically. The psychiatrist orders a pregnancy blood test which comes back negative, but her serum prolactin level is 115 ng/mL. What could explain why J.J. believes she is pregnant?

The negative pregnancy test proves J.J. is not pregnant (assuming no error by the laboratory). Her symptoms are indicative of hyperprolactinemia, another potential adverse effect of D_2 receptor antagonism from antipsychotic therapy. As her prolactin level increased, it caused J.J. to become amenorrheic and cause her to lactate. Although not a common adverse effect of most atypical antipsychotics, risperidone (and paliperidone) is similar to the typical antipsychotics in their propensity to increase serum prolactin.

CASE 85-1, QUESTION 20: How should J.J.'s hyperprolactinemia be treated?

Ideally the treatment of antipsychotic-induced hyperprolactinemia involves a dose reduction of the offending agent. As J.J. was increased to 4 mg twice daily due to an insufficient response to a lower dose, this may not be possible. If a dose reduction cannot be done safely, then a change in antipsychotic to one with a lower risk of hyperprolactinemia should be considered. If this too is not clinically appropriate for the patient, then addition of a dopaminergic agonist may be considered, such as amantadine. This should be done cautiously as a strong dopaminergic agonist, such as bromocriptine, may exacerbate her psychosis. There are also data available on using aripiprazole augmentation to treat hyperprolactinemia from antipsychotics, but this might be considered after other agents have been tried, unless J.J. appears to need a stronger antipsychotic regimen.

Weight Gain

Although the development of the SGAs was supposed to free us from the concern of the extrapyramidal adverse effects of the FGAs, many of the newer agents such as clozapine, olanzapine, quetiapine, and risperidone showed a tendency to, like the low-potency typical first-generation agents, cause substantial weight gain.[65] This substantial weight gain tended to occur to the greatest extent in the first few months of treatment, with a certain segment of those treated gaining more than 20 lb.[179] One study showed that 15.4% of those patients treated with olanzapine had weight gain greater than or equal to 7% of their body weight in the first 6 weeks of treatment.[180] It soon became apparent that clozapine and these newer SGAs had the potential to increase body weight and serum triglyceride levels,[65–68] and therefore potentially cause glucose dysregulation as well.[71,181,182] Patients suffering from schizophrenia are already prone to an earlier death than nonmentally ill patients due to their physical health and inherent sedentary lifestyle; therefore, weight gain may be an even more critical issue than the potentially stigmatizing occurrence of tardive dyskinesia.[156,183]

Numerous mechanisms have been theorized to explain the weight gain induced by the SGAs. These include histamine (H_1) receptor antagonism,[184,185] serotonin antagonism at 5-HT_{2c} with a possible genetic predisposition in some,[186,187] muscarinic antagonism which could possibly lead to increased consumption of sugary beverages or “thirsty” calories,[188] and impairments in plasma leptin secretion.[189–191] Concomitant medications, such as valproic acid, lithium, mirtazapine, some antihistamines, and tertiary tricyclic antidepressants, can also increase body weight by synergistic pharmacologic effects.[70,192]

Hyperglycemia and Diabetes Mellitus

It is unclear whether there are direct actions by SGAs involved in the development of diabetes mellitus. However, it is clear that weight gain, increased triglycerides, or decreased insulin sensitivity due to SGAs may cause an increased frequency or earlier onset of this endocrine disorder.[71,181,193–195] An early study showed a moderate correlation ($r = 0.60$, $p =.03$) between serum insulin and clozapine levels,[196] whereas Lund and associates showed an approximately 2.5 times greater risk of diabetes mellitus and hyperlipidemia in patients agents 20 to 34 years old treated with clozapine versus FGAs.[197] Other retrospective studies in veterans also suggested a slightly greater prevalence of diabetes in patients less than 40 years old on the SGAs clozapine, olanzapine, quetiapine, or risperidone (OR =1.09; CI=1.03–1.15) than those on FGAs[181] and an incidence of diabetes mellitus approximately 1.5 times greater in patients treated with olanzapine, risperidone, or quetiapine than with typical, mostly low-potency, antipsychotics.[71] Guidelines stress the need to monitor these patients routinely for glucose dysregulation, weight gain, and hyperlipidemia.[193,198]

Dyslipidemia

Treatment-emergent increases in both serum triglycerides and total serum cholesterol may occur with use of antipsychotics. The initial reports were of increased serum triglycerides with clozapine,[66,68,199] a notation of this phenomenon in the package insert for quetiapine, and reports of this occurring in patients taking olanzapine.[67] Risperidone does not raise serum triglycerides as

severely as clozapine[199], and ziprasidone has negligible effects on serum triglycerides.[200,201] Aripiprazole resulted in lowered serum triglyceride levels compared to placebo in pooled double-blind trials.[202] Average serum triglycerides with clozapine, olanzapine, or quetiapine tended to increase by approximately 60 to 70 mg/dL between studies.[66–67,70] Extreme elevations in serum triglycerides (>1,000 mg/dL) have been noted in some patients and were often associated with acute pancreatitis (Table 85-12).[69]

CASE 85-1, QUESTION 21: What other metabolic effects need to be monitored in JJ while she is receiving antipsychotic treatment? What are the risks of these effects in patients receiving these medications?

J.J., as with all patients receiving antipsychotics, is at risk of developing potentially significant weight gain, glucose irregularities including diabetes mellitus type 2, and dyslipidemia, especially hypertriglyceridemia. The risk varies among the agents, with SGAs generally thought to be at a higher risk than with FGAs. Risperidone, which J.J. is currently receiving, is often considered to be at a mid-level risk of these effects compared to some of the other SGAs. Other possible risk factors include the patient's diet and exercise, family history of diabetes and cholesterol problems, and others.

CASE 85-1, QUESTION 22: The psychiatrist decides to change JJ from risperidone to an agent with a lower risk of hyperprolactinemia. He starts JJ on olanzapine, titrating up to 20 mg/day while removing the risperidone. What would be the appropriate monitoring for J.J. upon initiation of olanzapine?

As olanzapine has a high risk of causing metabolic adverse effects in patients, J.J. should be monitored closely for the development of these effects. Her weight should be checked very closely, especially at baseline and over the first few months of treatment. Monthly, if not more frequently, weights should be measured during this time. In addition, her serum glucose and/or HbA1c along with her serum lipid panel should be checked at baseline and then in 3 months for any changes, with an interim serum glucose measurement around 1 to 2 months. Her blood pressure should also be monitored for any changes, especially if her weight increases significantly. If any increases or abnormalities are noted in these parameters, they should be addressed appropriately before becoming a medical concern.

CASE 85-1, QUESTION 23: After 2 months on olanzapine, J.J. returns to the clinic complaining that she's always eating and doesn't fit into her clothes from last summer. Her weight today is 151 lb (BMI = 25.9 kg/m^2), an increase from her weight prior to olanzapine of 139 lb (BMI = 23.9 kg/m^2). J.J.'s parents are also concerned as they have never seen her eat this much in her life. She is currently doing well on the medication, with no psychotic symptoms noticed over this time. They ask whether this appetite and the weight gain are from the olanzapine, and whether there is anything that can be done about it.

Olanzapine could certainly be the cause of her recent weight gain, because it has one of the higher risks of causing weight gain among the SGAs. A 12-lb weight gain is certainly possible with this medication. As J.J., and her parents, has noticed an increase in her appetite since starting the medication, this makes it even more likely olanzapine is involved. Although there are no proven treatments for antipsychotic-induced weight gain, there are some interventions that could be implemented. J.J. should be given an appointment with a nutritionist to review her diet, and she should also be encouraged to increase her exercise on a regular basis, whether at a gym or even by adding 20- to 30-minute walks 4 to 5 days a week.

Table 85-12

Metabolic Monitoring Protocol for Antipsychotics

	Baseline	Week 4	Week 8	Week 12	Week 16	Week 20	Week 24	Quarterly	Annua
Personal or family history	X								X
Weight (BMI)[a]	X	X	X	X	X	X	X	X	
Waist circumference	X								X
Blood pressure	X			X					X
Fasting plasma glucose	X	X (once during this period)		X			X	X (for first year)	X
Fasting lipid profile	X			X			X		X

More frequent assessments may be warranted based on clinical status.

[a] Some references recommend weekly monitoring for first 6 weeks after initiation to determine patients at risk more significant long-term weight gain, especially with agents with higher risk of causing weight gain.

Adapted from American Diabetes Association et al. Consensus development conference on antipsychotic drugs obesity and diabetes. Diabetes Care. 2004;27(2):267–272; Hasnain M et al. Metabolic syndrome associated schizophrenia and atypical antipsychotics. Curr Diab Rep. 2010;10(3):209–216. doi:10.1007/s11892-010-0112-8; Ki BJ et al. Association between early and rapid weight gain and change in weight over one year of olanzapine therap patients with schizophrenia and related disorders. CASE 85-1, QUESTION 24: A month later, J.J. returns to the clinic. Blood work done a few days ago shows her fasting serum glucose to be 214 mg/dL, which is an increase from 132 mg/dL 4 months ago. Her HbA1c has also increased from 5.9% to 7.1% over this time. A serum lipid panel shows her total cholesterol is 256 mg/dL, her direct LDL cholesterol is 117 mg/dL, her HDL is 34 mg/dL, and her triglycerides are 997 mg/dL. Are these changes potentially related to J.J.'s antipsychotic treatment and if so, how should they be managed?

Increases in serum glucose and lipids, especially triglycerides, are possible with SGAs, and olanzapine in particular. As her glucose and A1c have increased since starting the medication, this makes it highly likely this is the cause. Although J.J.'s LDL and HDL cholesterol measurements are not ideal, they are not as concerning as her very elevated triglyceride level. At this high of a level of triglycerides, there is the concern of possible pancreatitis. J.J. should be asked about any upper abdominal pain or other possible symptoms.

Although we could treat her increased serum glucose and lipids with appropriate medications for each concern, another consideration would be to change J.J. from olanzapine to another SGA with a lower risk of metabolic problems. This would need to be done after considering the risk of J.J.'s possible psychiatric decompensation from changing her antipsychotic treatment.

Medical Comorbidity

Currently, metabolic syndrome is seen as a major concern when treating schizophrenia, and it is recommended that patients receiving SGAs must be routinely monitored for weight gain, changes in fasting serum lipids, or signs of glucose dysregulation.[193,198,203] Some estimates of the prevalence of metabolic syndrome in patients with schizophrenia range from 18.8% to approximately 40% of those tested.[204] As medication-naïve patients are already at a high risk for developing metabolic syndrome,[205] we should strive to minimize the chance or worsening their situation. Furthermore, since weight gain with antipsychotic medication and its secondary metabolic complications tends to occur rapidly, patients should receive more frequent assessments for this when they are first started or switched to a new antipsychotic medication. Medication use evaluations to make sure this necessary monitoring is performed may be helpful.[206]

Moreover, effective pharmacotherapy carries with it a potential for serious adverse metabolic effects such as obesity, hypertriglyceridemia, and resulting glucose dysregulation as well as movement disorders such as akathisia, drug-induced parkinsonism, and tardive dyskinesia. One study showed metabolic disorders occur more than 3 times (3.7; 95% CI = 1.5–9.0) as much in patients with schizophrenia as compared to nonpsychiatrically ill controls.[207] In fact, cardiovascular disorders are the main reason patients with schizophrenia tend to die at a younger age than their peers.[208]

Another concern is that, along with known genetic factors,[209] metabolic syndrome issues such as increased weight, serum leptin, lipids, and glucose are known risk factors for venous thromboembolism (VTE) which also may occur in association with antipsychotic pharmacotherapy.[210,211] The most established link is to the use of clozapine,[212] which is one of the most metabolically problematic agents. However, even more metabolically benign antipsychotics may eventually be linked to the increased occurrence of VTE.[213] Pulmonary embolism is a well-documented variant occurring with antipsychotics.[214,215] As VTE related to antipsychotics is likely rare, the benefit-to-risk ratio should be kept in perspective.[216]

Other cardiovascular effects can be problematic when utilizing antipsychotic pharmacotherapy. Of concern, olanzapine, risperidone, and quetiapine have been associated with a three-fold increased likelihood of cerebrovascular accidents (CVAs) and transient ischemic attacks during the first 6 months of treatment in elderly patients.[217,218] Other antipsychotics have also been implicated.[219] Such events could relate to the slightly higher risk of death in elderly patients receiving these medications.[220] As a result, all antipsychotics have a black box warning from the US FDA regarding an increased risk of CVAs in elderly patients taking these medications.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is a rare, but potentially fatal complication of antipsychotic therapy that can occur due to treatment with any antipsychotic or abrupt cessation of a dopamine agonist. Therefore, early recognition and management are crucial. There are numerous diagnostic scales to ensure accurate diagnosis of NMS for research purposes, but the most widely utilized in clinical practice is the DSM-5 criteria. NMS is associated with high fever (103°F–104°F), muscular rigidity, altered consciousness, and highly elevated creatinine phosphokinase (CPK) often greater than 1,000 mcg/L. Other signs are drooling, difficulty swallowing, fast heart rate (greater than 100 bpm) profuse sweating, incontinence, and labile blood pressure. It is treated by immediate cessation of antipsychotic therapy, supportive care, and the administration of medications such as dantrolene sodium, biperiden, or bromocriptine. Combination antipsychotic therapy was found in 39% of all NMS cases.[221] Some believe that physical exhaustion and dehydration predispose a patient to develop NMS, so it is important that patients on antipsychotics be cautioned to take proper caution in hot weather. Also, the effects of antipsychotics on the hypothalamus (which regulates temperature and food intake among other activities) and the "body-secretion" drying activities of anticholinergic medications increase the danger of heat exhaustion in these patients.[222]

CASE 85-1, QUESTION 25: J.J.'s psychiatrist decides that in light of her weight gain and worsening glucose and lipid profiles, he is going to change her from olanzapine to lurasidone, titrating her up to 80 mg/day. She did well with the medication change. A few weeks after starting the lurasidone, her parents take JJ into the ER one evening concerned she has meningitis as she feels feverish, is sweating, seems confused, and has a stiff neck. The ER exam shows JJ has a fever of 103.1°F, blood pressure of 176/98 mm Hg, pulse of 136 bpm, respiratory rate of 36 bpm, a stiff neck that is not painful, and is sometimes incoherent when answering questions, but shows no outward signs of psychosis. She also is sweating profusely despite the air conditioning in the ER room. Laboratory work is ordered and returns a couple hours later. J.J.'s chemistries are normal except for a creatinine phosphokinase (CPK) of 5,960 mcg/L, a normal CBC, and a normal serum glucose. Repeat vital signs 2 hours after she comes to the ER show a fever of 103.2°F, blood pressure of 96/62 mmHg, pulse of 146 bpm, and a respiratory rate of 39 bpm. What is the most likely cause of J.J.'s presentation at this time and why? How should J.J. be managed?

J.J. is most likely suffering from neuroleptic malignant syndrome (NMS) from lurasidone. Although NMS can occur at any time during treatment with any antipsychotic, the timing of this episode shortly after beginning the medication makes it more likely. As she does not have pain in her neck or an elevated WBC, it is not likely meningitis as her parents feared (though this should be definitively ruled out). The high fever, labile blood pressure, tachycardia, sweating, confusion (without psychosis), and highly elevated CPK are indicative of NMS. J.J. will need to be admitted to the hospital as NMS can be life-threatening. As she will need to stop taking all antipsychotics for up to 2 weeks, she will most likely require hospitalization during this time as her psychosis is likely to return. During the acute treatment period, she will likely need treatment for the NMS with either dantrolene (for the fever) or bromocriptine (a dopamine agonist), as well as other measures as needed for her fever, elevated blood pressure, etc. During the longer period without antipsychotic treatment while waiting for the NMS to resolve, J.J. will likely need treatment with sedatives such as benzodiazepines as we cannot actively treat her schizophrenia.

CASE 85-1, QUESTION 26: During the subsequent admission for her episode of NMS, J.J. is eventually started on aripiprazole for her schizophrenia. A few days into titrating the medication to an effective dose, she develops some mild stiffness in her arms, most likely some mild parkinsonism. Fearful that this is the NMS returning, J.J. now refuses to take any antipsychotics. Her psychiatrist decides to start her on a LAIA form of aripiprazole, but notices there are two different versions of the medication available. Which of these two forms would be the better choice for J.J. at this time?

Ideally we would be able to stabilize J.J. on an oral form of aripiprazole prior to conversion to a LAIA form of the medication, but her nonadherence makes that unlikely. Both forms of aripiprazole LAIA require an overlap of oral medication during initiation: 14 days for the monohydrate salt and 21 days for the lauroxil salt. The main concern is the dosing of the LAIA, however. The monohydrate salt has a single dose for all patients, except in cases of renal impairment of P450 inhibitors or inducers. The lauroxil salt is dosed based upon a conversion from the dose of oral aripiprazole the patient is currently receiving. As J.J. was never stabilized on an oral dose of aripiprazole before she stopped taking the medication, it would be very difficult to convert her over to an equivalent dose of the lauroxil LAIA. Therefore, it would be easier to initiate the monohydrate salt version at its usual dose of 400 mg every month and then try to provide coverage for the initial 14-day window recommended for the product. Regardless of which form is used, J.J. should be monitored for the development of the parkinsonism she had when being titrated on the oral form of aripiprazole.

CASE 85-1, QUESTION 27: Over the next few months, J.J. is maintained on aripiprazole monohydrate

LAIA 400 mg/month. As her symptoms improved but she was still showing some signs of daily auditory hallucinations, haloperidol 5 mg/day was added to her regimen. Her hallucinations subsided within a couple weeks after an increase to 10 mg/day of haloperidol, but now J.J. comes in with her parents to the ER attached to the clinic. J.J.'s neck is turned clockwise to her right shoulder, and she is unable to move her head back to her centerline and look forward. J.J. says her neck hurts a lot and she wants this feeling to go away. What is the most likely reason for J.J.'s current complaint and how should it be managed?

J.J. is most likely experiencing a dystonic reaction, or dystonia, from the recent addition and increase in her haloperidol dose. The specific type of dystonia she has is called torticollis, which is dystonia causing the muscles of the upper spine to contract and cause a twisting motion of the neck. This is another type of EPS, and as seen in J.J. here, can often be painful due to the strong muscle contraction. FGAs are more likely to cause this problem than SGAs, so the timing of the reaction to the addition of haloperidol makes sense.

Acutely, J.J.'s dystonia needs to be treated as quickly as possible as it is painful to her. Oral medications could take an hour or longer to work, so an injectable agent is preferred for more rapid action. As with drug-induced parkinsonism, the agent of choice is an anticholinergic medication to offset the EPS. Most ER's will have either benztropine or diphenhydramine (which has appreciable anticholinergic effects) readily available in an IM/IV form for a case like this. Atropine, while also likely available, is generally not used due to greater systemic and cardiac effects. Benzodiazepines can also be used in IM/IV forms if needed, as they too will help relax the contracted muscles and help J.J. calm down.

Additionally, J.J.'s medication regimen may need to be adjusted to prevent a future dystonic reaction. A reduction in her haloperidol dose may be needed, or adjunctive oral anticholinergics added to her regimen as prophylaxis.

CASE 85-1, QUESTION 28: J.J. has been continued on the combination of aripiprazole monohydrate LAIA and haloperidol over the next 8 years. Over time her symptoms have returned periodically, never requiring a hospitalization but necessitating gradual increases in her haloperidol to 15 mg/day. J.J. now presents to the clinic with "shakes in my hands" that are bothering her. During the physical examination, J.J. is noted to have facial grimacing, darting movements of her tongue, lip-smacking, and twisting movements in her hands. The movements in her hands seem to disappear when she grabs an object or performs other activities with her hands. What is the most likely cause of these movements in J.J.?

These movements are most likely an early form of tardive dyskinesia. Haloperidol, as a high-potency FGA, has a high risk of causing this movement disorder over time: approximately 3% to 5% per year of use, or 24% to 40% risk in J.J. The symptoms we are observing in J.J. are consistent with those movements seen in tardive dyskinesia which presents with arrhythmic choreoathetoid "snake-like" movements of the orofacial areas, limbs, and trunk. The fact that the irregular hand movements stop or decrease when J.J. performs a conscious task with her hands is also indicative of tardive dyskinesia.

CASE 85-1, QUESTION 29: What can be done to treat the tardive dyskinesia seen in J.J. at this time?

Although there are no definitive treatments for tardive dyskinesia, there are some strategies that might help to alleviate the problem. Slow decreases in her haloperidol dose over time may help these movements decrease; a rapid reduction in the dose may acutely worsen the problem, so this should be avoided. If the movements persist despite lowering the dosage or discontinuing the haloperidol, there are some data supporting the use of clozapine to treat the dyskinesia and schizophrenic symptoms. This should be considered cautiously in light of the other concerns related to clozapine treatment.

Inadequate Response

The patient with chronic schizophrenia must be evaluated in a systematic fashion to discern whether past medication trials were indeed medication failures. Medication nonadherence, intolerance, and inadequate dosing may often be documented as failed trials. Patients with schizophrenia have been shown to have a deficit in perspective habitual memory which may cause difficulty in remembering whether they took their medications.[223] This could result in either missed or doubled dosages. An in-depth assessment of medication adherence should be conducted in a nonpunitive and collaborative fashion with the patient. Outreach for collateral information should also be undertaken after acquiring appropriate releases of information. Clinical deterioration often occurs slowly and insidiously with incomplete medication adherence.[224] Poor therapeutic relationship and social supports may also lead to poor adherence in patients with schizophrenia.[225] Other important predictors include lack of insight, concomitant substance abuse, a short illness duration, issues with discharge planning and

---

environment,[226] as well as higher levels of hostility.[227] Patients who have had difficulties with medication adherence in the past should be offered treatment with a long-acting injectable antipsychotic.

A trial of an antipsychotic should be continued for at least 4 to 6 weeks at a therapeutic dosage after initial partial response of symptoms. Switching and augmentation strategies should only be considered after symptoms fail to fully respond to an adequate trial. Patients may wind up in a stalled cross-titration, possibly due to a transition in care, and be continued on multiple antipsychotics. This highlights the need to carefully tease out the patient’s medication experience and transition to effective monotherapy to avoid increased adverse effects, pill burden, and cost for the patient.

Between 20% and 30% of patients remain unresponsive despite multiple antipsychotic trials. The most commonly adopted and most stringent criteria for antipsychotic treatment refractoriness were proposed in the landmark trial conducted by Kane and colleagues that resulted in clozapine's approval in the U.S. market. Treatment refractoriness was defined as: (1) at least three periods of treatment in the preceding 5 years with antipsychotics from two chemical classes at dosages equivalent or greater to 1,000 mg/day of chlorpromazine for a period of 6 weeks, (2) no symptom-free period within 5 years, and (3) BPRS total score >45.[57,228]

Clozapine is the most efficacious medication in patients with treatment-resistant schizophrenia and should be considered in all patients who fail to respond to at least two adequate antipsychotic trials.[57,107,172,229] It is also the treatment of choice for those at high risk for suicide or violence, or in patients with TD.[102,230] Despite its superior efficacy, clozapine is often underutilized in the treatment of resistant schizophrenia due to its adverse effect burden. Close monitoring and follow-up are necessary to ensure safe and effective use of clozapine. Baseline monitoring should include a physical examination (weight, blood pressure, waist circumference), HbA1c or fasting blood glucose, a fasting lipid panel, liver function tests, serum creatinine, blood urea nitrogen levels and pregnancy test, if indicated. Clozapine has a unique adverse effect profile that ranges from common bothersome adverse effects to life-threatening adverse effects listed in its five black box warnings. The black box warnings caution for risk of agranulocytosis, seizures, myocarditis, other adverse cardiovascular and respiratory effects, and increased mortality in elderly patients with dementia-related psychosis.

Agranulocytosis is a rare, yet potentially life-threatening, hematologic reaction affecting approximately 1% of clozapine-treated patients. It is defined as a drop in neutrophil count below 500 cells/mm^3. Agranulocytosis is not dose-related and can occur at any point in treatment though the risk is higher within the first 6 months of therapy. Clozapine may also cause mild-to-severe neutropenia (ANC 500–2,000 cell/mm^3). Clozapine-induced neutropenia and agranulocytosis may be in part due to selective effect on precursors of polymorphonuclear leukocytes; however, the mechanism remains to be fully elucidated. Clozapine is only dispensed through the clozapine risk evaluation and monitoring strategy (REMS) to ensure ANC values are within range prior to dispensing clozapine. The pharmacy, patient, and provider must all be enrolled in the clozapine REMS program. Monitoring of the absolute neutrophil count (ANC) must occur 7 days prior to initiation of clozapine and weekly thereafter for the first 6 months. Monitoring frequency can be reduced to biweekly for the next 6 months if all ANC values are within range (>1,500/μL). Frequency of blood draws may be decreased to every 4 weeks if all values remain within range after 6 months of biweekly monitoring, and be maintained at every 4 weeks for the duration of clozapine treatment if no abnormalities are seen. Certain ethnic groups, including patients of African and Middle Eastern descent, may average a lower ANC value than normal ranges, called benign ethnic neutropenia (BEN). The clozapine REMS program allows for lower ANC values to compensate for patients diagnosed with BEN as they do not suffer from repeated or severe infections as a result of their low baseline ANC values. Severe neutropenia can be deadly due to the body's inability to fight off infection. This is a medical emergency that requires the abrupt discontinuation of clozapine. In other cases, clozapine should be discontinued gradually over a period of 2 weeks or longer, to prevent cholinergic rebound (sweating, headache, nausea, vomiting, diarrhea) or recurrence of psychotic symptoms. The patient should not be rechallenged on clozapine after agranulocytosis, but patients can be successfully rechallenged after neutropenia.[231] More information can be found at https://www.clozapinerems.com/ (Table 85-13).

Seizure risk associated with clozapine is a dose-related phenomenon. Risk of seizure is 4.4% at a dose of 600 mg and several case reports implicate serum levels greater than 500 to 1,300 ng/mL with higher risk of seizure.[232,233] Prophylactic use of antiepileptic drugs (AED) is generally not recommended.[234] However, patients that experience a seizure on clozapine can be safely continued on a lower dose of clozapine and initiated on an AED. Valproate and lamotrigine are preferred over carbamazepine due to its risk of agranulocytosis and extensive interaction profile.[233] Myocarditis is a potentially fatal hypersensitivity reaction that can occur approximately 3 weeks after initiation of clozapine. Diagnosis is confounded by the variable and nonspecific signs and symptoms of its presentation, but the incidence is estimated to fall between <0.1 and 3%.[235] The monitoring protocol proposed by Ronaldson and colleagues consists of obtaining baseline troponins, C-reactive protein (CRP), and an ECG, and then monitoring troponin and C-reactive protein on days 7, 14, 21, and 28 of treatment. In the case of mild elevation in troponins or CRP, persistent tachycardia, or signs or symptoms resembling infection, daily troponins and CRP should be drawn until symptom resolution. Clozapine should be discontinued if troponins reach twice the upper limit of normal or if CRP > 100 mg/L.[61] Successful rechallenge may be possible after symptoms resolve.[236,237]

The black box warning describing “other adverse cardiovascular and respiratory effects” references the risk of orthostatic hypotension associated with clozapine. Approximately 9% of patients will experience orthostatic hypotension, but tolerance develops over 4 to 6 weeks.[165] Risk is higher during initiation which necessitates the slow titration beginning at 12.5 mg twice daily and increasing at the rate of 25 to 50 mg/day or slower. Clozapine must also be retitrated after a gap in therapy of greater than 2 days to prevent significant orthostasis and risk of falls. Patients should be counseled to make slow transitions from prone or seated positions and maintain adequate fluid and salt intake. In patients with persistent dizziness and orthostasis after titration where dose reduction is not an option, treatment with the mineralocorticoid, fludrocortisone, may be an option.[165]

Clozapine is also associated with frequent, bothersome adverse effects that, if left unaddressed, can greatly impact quality of life. Constipation is a common, yet often overlooked adverse effect of clozapine that can result in serious complications including paralytic ileus, small-bowel perforation, or death secondary to aspiration of gastric contents. It affects between 14% and 60% of patients taking clozapine. Patients should be screened at every visit for bowel habits and providers should have a low threshold for initiating a bowel regimen. Bowel regimens consist of bulk-forming laxatives and increased fluid intake, stool softeners, or short-term use of stimulant laxatives or enemas. Anticholinergic adverse effects of clozapine can result in GI hypomotility, small-bowel obstruction, and ileus. These are serious concerns that may occur in up to 0.3% of clozapine-treated patients. Adjunctive anticholinergic agents and opioids should be limited and clozapine dose tentatively decreased, or held in cases of ileus. Sedation is usually more pronounced when first initiating clozapine and can be managed by slowing the rate of titration and consolidating the dose to bedtime. As previously described, a benign tachycardia can also result from clozapine use, but patients also presenting with flu-like symptoms, dyspnea, fever, and chest pain should have further work-up for myocarditis. Sialorrhea is an embarrassing adverse effect that in the extreme can result in sleep disruption or aspiration pneumonia. Treatment options include tentative dose reduction or nonpharmacologic management, such as placing a towel on their pillow, as first line. Topical anticholinergic agents (ipratropium 0.03%–0.06% dosed 1–2 sprays sublingually or 1–2 atropine eye drops in 1 ounce of water swished and spit) are preferred over systemic anticholinergics (benztropine 0.5–2 mg HS or glycopyrrolate 1–2 mg) or the α-2 adrenergic agent, clonidine.[238] Serious cases may be treated with botulinum toxin injected into each parotid gland.[238] Nocturnal enuresis may also be underreported due to embarrassment. Management includes avoiding fluids in the evening, voiding prior to bed, and setting alarms to schedule nocturnal voiding. Desmopressin may also be effectively utilized, but the patient must be monitored for hyponatremia secondary to its use.[165]

Table 85-13

Clozapine Monitoring Requirements

ANC Level	Treatment Recommendation	ANC Monitoring
Normal Range for a New Patient General Population ■ ANC ≥ 1,500/μL	Initiate treatment ■ If treatment interrupted: ■ <30 days, continue monitoring as before ■ ≥30 days, monitor as if new patient	Weekly from initiation to 6 months ■ Every 2 weeks from 6 to 12 months ■ Monthly after 12 months
BEN Population ■ ANC ≥ 1,000/μL ■ Obtain at least two baseline ANC levels before initiating treatment		
Mild neutropenia (1,000–1,499/μL)[a]	General Population ■ Continue treatment	General Population ■ Three times weekly until ANC ≥1,500/μL ■ Once ANC ≥1,500/μL return to

		patient’s last “Normal Range” ANC monitoring interval[b]

	BEN Population
	■ Mild neutropenia is normal range for BEN population, continue treatment
	■ Obtain at least two baseline ANC levels before initiating treatment
	■ If treatment interrupted
	  ■ < 30 days, continue monitoring as before
	  ■ ≥ 30 days, monitor as if new patient
	■ Discontinuation for reasons other than neutropenia
		BEN Population
		■ Weekly from initiation to 6 month
		■ Every 2 weeks from 6 to 12 months
		■ Monthly after 12 months

Moderate Neutropenia (500–999/µL)[a]	General Population ■ Recommend hematology consultation ■ Interrupt treatment for suspected clozapine-induced neutropenia ■ Resume treatment once ANC normalizes to ≥1,000/µL	General Population ■ Daily until ANC ≥1,000/µL, then ■ Three times weekly until ANC ≥1,500/µL ■ Once ANC ≥1,500/µL check ANC weekly for 4 weeks, then return to patient’s last “Normal Range” ANC monitoring interval[b]
	BEN Population ■ Recommend hematology consultation ■ Continue treatment	BEN Population ■ Three times weekly until ANC ≥1,000/µL or ≥patient’s known baseline. ■ Once ANC ≥1,000/µL or patient’ known baseline, check ANC weekly for 4 weeks, then return to patient’s last “Normal BEN Range” ANC monitoring interval.[b]
Severe Neutropenia (<500/µL)[a]	General Population ■ Recommend hematology consultation ■ Interrupt treatment for suspected clozapine-induced neutropenia ■ Do not rechallenge unless prescriber determines benefits outweigh risks	General Population ■ Daily until ANC ≥1,000/µL ■ Three times weekly until ANC ≥1,500/µL ■ If patient rechallenged, resume treatment as a new patient under “Normal Range” monitoring once ANC ≥1,500/µL
	BEN Population ■ Recommend hematology consultation ■ Interrupt treatment for suspected clozapine-induced neutropenia ■ Do not rechallenge unless	BEN Population ■ Daily until ANC ≥500/µL ■ Three times weekly until ANC ≥ patients established baseline ■ If patient rechallenged, resume treatment as a new patient

	prescriber determines benefits outweigh risks	under “Normal Range” monitoring once ANC ≥1,000/μL or at patient’s baseline

[a] Confirm all initial reports of ANC less than 1,500/μL (ANC <1,000/μL for BEN patients) with a repeat ANC measurement within 24 hours

[b] If clinically appropriate

BEN, Benign Ethnic Neutropenia

Clozaril (clozapine tablets) [package insert]. East Hanover, NJ: Novartis Pharmaceuticals Corporation; September 2015.

CASE 85-1, QUESTION 30: J.J.’s psychiatrist decides to start J.J. on clozapine and remove all other antipsychotics in light of her tardive dyskinesia and past failures and adverse effects with other antipsychotics. What adverse effects of clozapine should be monitored for in J.J.?

Any patient started on clozapine should be monitored for agranulocytosis and metabolic adverse effects, among others. As J.J. has a history of metabolic adverse effects (weight gain, increased glucose, and increased triglycerides) with other antipsychotics, these are of particular concern with using clozapine with her as clozapine has the highest risk of these adverse effects. J.J. should also be counseled about orthostatic hypotension, sedation, anticholinergic effects (especially constipation), and sialorrhea.

CASE 85-1, QUESTION 31: Prior to initiating clozapine therapy, what laboratories and other tests should be performed on J.J.?

Clozapine therapy requires a baseline absolute neutrophil count (ANC) prior to starting the medication to ensure the patient has an adequate number of neutrophils prior to initiation. In addition, her weight, waist circumference, serum glucose/HbA1c, and lipid panel should be measured to monitor for the development of metabolic adverse effects. Baseline liver and kidney function tests should also be measured. A pregnancy test should also be performed, especially if there is any chance that J.J. could be pregnant.

CASE 85-1, QUESTION 32: Once J.J. is started on clozapine, how should she be monitored? What parameters should be checked and how frequently?

Clozapine treatment requires weekly ANC checks for at least the first 6 months of treatment. Assuming no problems with her ANC values (ANC ≥ 1,500/ μL), she can then go to ANC checks every other week for 6 months, and then ANC checks once every 4 weeks thereafter. In addition, her weight should be monitored at least monthly (and perhaps weekly) for the first few months of treatment, along with at least quarterly serum glucose and lipid panel checks. She should also be asked about any problems with orthostasis (dizziness), constipation, sedation, and drooling during any office visits.

Serum Concentration Monitoring

Data supporting a strong correlation between antipsychotic serum concentrations and efficacy are lacking.[239] Therefore, routine therapeutic drug monitoring of antipsychotic serum concentration is not recommended in clinical practice. The exception is clozapine, which has sufficient data to support a higher rate of response at levels above 350 ng/mL.[173,240] Monitoring of serum levels is appropriate in the following clinical scenarios:

1. Psychiatric decompensation on a previously effective dose
2. Poor response to medication despite adequate dose and trial duration
3. Unexpected adverse effects while on a previously tolerated dose
4. Addition or withdrawal of an interacting medication
5. Patients with potentially altered PK (e.g., medically compromised, children, elderly)
6. Suspected medication nonadherence

Nonantipsychotic Agents

Antipsychotics are generally the treatment of choice for most patients with schizophrenia. However, in some situations, other medications may be needed and appropriate for use. Benzodiazepines may be appropriate in patients with acute agitation, as described previously. Other medications, such as mood stabilizers and antidepressants, may be useful for some patients based upon their clinical symptoms and presentation.

MOOD STABILIZERS

The mood stabilizers lithium, carbamazepine, valproic acid, and lamotrigine have been studied for use in schizophrenia. These medications are frequently used as an adjunct to antipsychotic treatment in schizophrenia in patients with affective symptomatology as well as core symptoms of schizophrenia. Evidence for these common practices is sometimes found to be equivocal or conflicting.

None of these mood stabilizers have shown efficacy as monotherapy for schizophrenia. Lamotrigine has been found to have modest effects in schizophrenic pathology as an adjunct to antipsychotic treatment but has little efficacy in treating the treatment-resistant patient.[241] Lithium was determined by a Cochrane review to have some benefit as an augmenting agent in lower quality studies, but replication in higher quality studies is needed.[242] A recent meta-analysis shows evidence that the practice of augmentation of antipsychotic medications with valproate yields significant improvements in patients treated for schizophrenia or schizoaffective disorder.[243] A recent Cochrane review does not recommend carbamazepine for augmentation of antipsychotics in the treatment of schizophrenia.[244] A need for further study of antipsychotic augmentation with mood stabilizers is warranted. Concomitant use should be carefully considered at this time given the potential for drug interactions, and additional adverse effect and pill burden.

ANTIDEPRESSANTS

Depression often presents in schizophrenia[37,245] and approximately 6% to 10% of patients with schizophrenia commit suicide in their lifetime.[29,246–248] Though controversial, there is evidence that antipsychotics may differ in their ability to treat depressive symptoms in schizophrenia[54,99,249,250] and many consider SGAs to be better for this syndrome than the FGAs.[250,251] Some of the advantages of SGAs in depression may be due in part to less antipsychotic-induced dysphoria or akinesia or effect on treating negative symptoms.[250,251] There is also substantial literature showing that adding an antidepressant may be a useful option in some depressed patients.[252] The divergent pattern of antidepressant response on numerous studies suggests that those patients whose positive symptoms are well controlled are more likely to respond favorably to antidepressant augmentation.[28] In one trial, the antidepressant bupropion did significantly worse than placebo in patients treated with thiothixene.[34]

Some also advocate for the possible effectiveness of antidepressant medication to decrease the severity of negative symptoms in schizophrenia.[253] One review found only 5 of 14 studies with SSRI antidepressants demonstrated efficacy in ameliorating negative symptoms; however, mirtazapine was promising in 4 of 6 trials.[252] Tricyclic antidepressants do not have robust evidence in treatment of negative symptoms.[254]

CASE 85-1, QUESTION 33: J.J. responds well to clozapine, taking a dose of 450 mg/day, with higher doses causing intolerable adverse effects in J.J. Over time, J.J. begins to become depressed as she realizes that her life has not gone the way she thought it would. Her psychiatrist assesses her as having depression secondary to her schizophrenia, and the decision is made to start her on paroxetine 20 mg daily. Is the addition of paroxetine appropriate for J.J.?

Although paroxetine is an appropriate treatment for depression, it is most likely not a good choice for J.J. There are data that show that paroxetine can cause anticholinergic adverse effects in patients, which could overlap any anticholinergic effects caused by clozapine. J.J. would need to be monitored for increased anticholinergic adverse effects, and possibly be treated for them (e.g., bowel regimen for constipation). Selection of an antidepressant with a lower risk of drug interactions, such as Escitalopram or Sertraline, would be more appropriate.

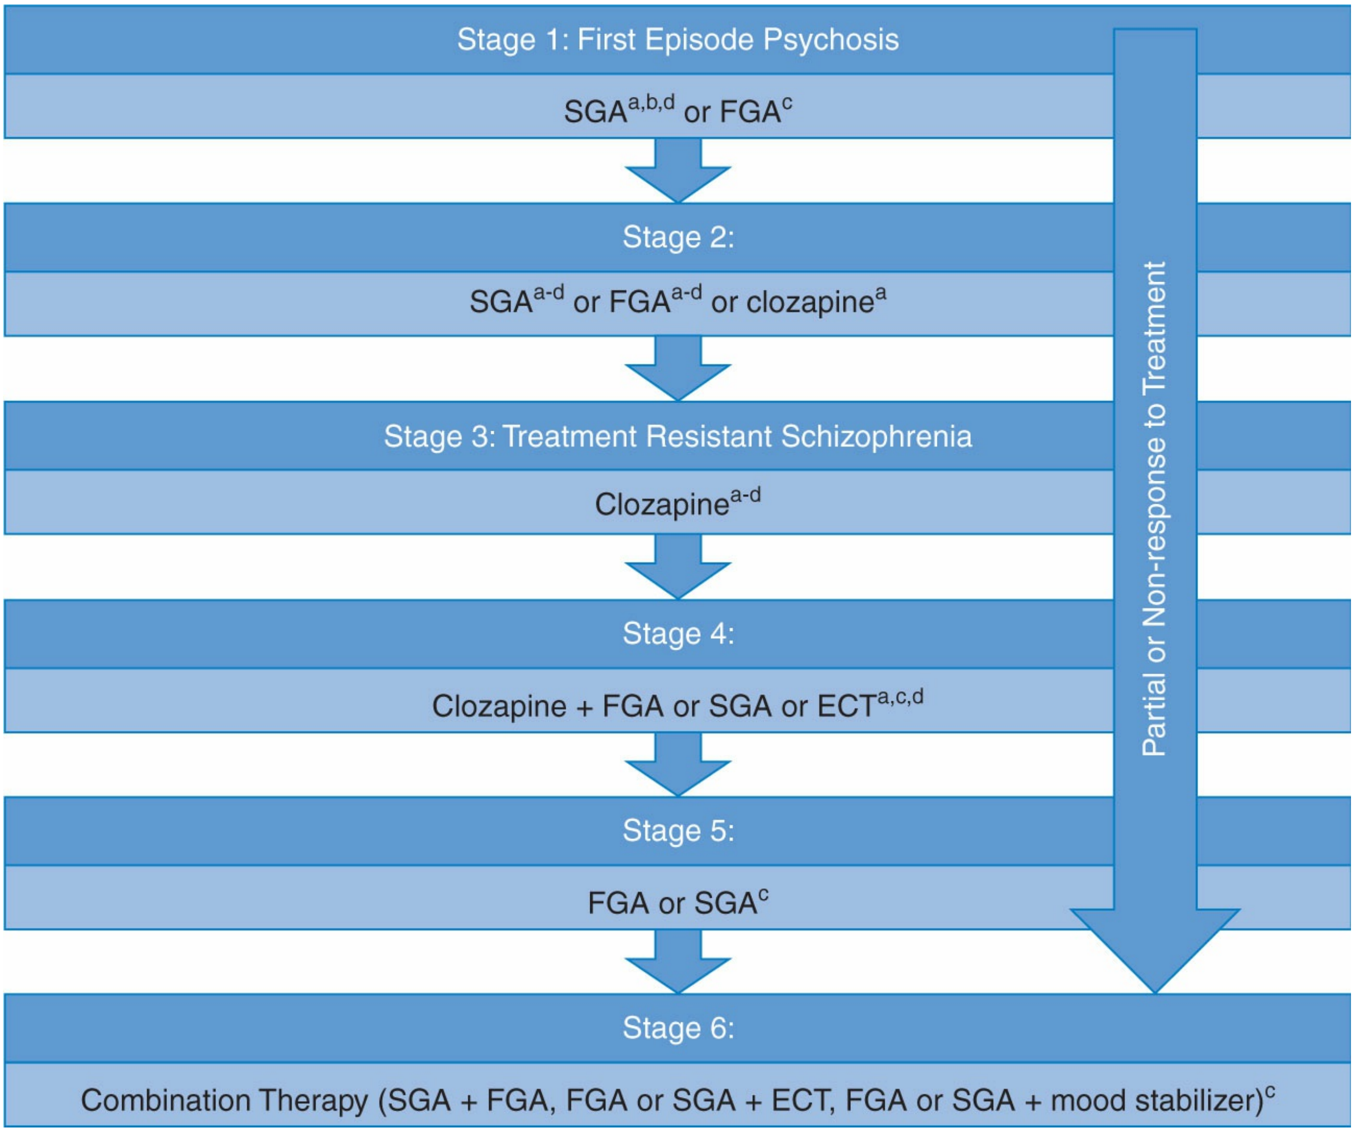
Treatment Guidelines for Schizophrenia

Clinical guidelines on the treatment of schizophrenia are published by a number of organizations. The most prolific and current guidelines at this time are the American Psychiatric Association (APA), Patient Outcomes Research Team on Schizophrenia (PORT), Texas Medication Algorithm Project (TMAP), and the National Institute for Health and Care Excellence (NICE) of the United Kingdom.[101–103,255] These guidelines are an excellent resource and starting point in ensuring evidence-based and safe care of patients with schizophrenia. However, it is important to keep in mind the level of evidence each organization requires to support a given treatment recommendation. The PORT guidelines have a threshold of at least two randomized controlled trials prior to publishing a treatment recommendation. The APA utilizes a less clearly defined process of systematically evaluating the literature, then rating clinical recommendations by the following coding system: (I) recommended with substantial clinical confidence, (II) recommended with moderate clinical confidence, and (III) may be recommended on the basis of individual circumstances. Other guidelines may also incorporate expert opinion[101,103] or consensus in areas which lack high level evidence, such as antipsychotic combination treatment or treatment after nonresponse to clozapine. The bottom-line is these guidelines provide a systematic framework for treatment, but should by no means be a substitute for clinical judgment and treating the unique clinical picture each individual presents. Any treatment decision should be aligned with the treatment team, caregivers, and most importantly—the patient. Even the most effective treatment is destined to fail unless the patient is invested and in agreement with their own treatment. Figure 85-2 is a consolidated view of the current guidelines on the use of antipsychotics in the treatment of schizophrenia.

CONSIDERATIONS IN SPECIFIC POPULATIONS

Pregnancy

The peak onset of schizophrenia in the female population coincides with peak childbearing age and unplanned pregnancies can be a concern.[256] Patients should be routinely educated on safe sexual practices, offered contraceptives if indicated, and receive pregnancy tests prior to prescription of antipsychotic medications. The general goals of treatment in pregnant patients are to thoroughly weigh the risks of teratogenicity with benefit of ongoing treatment and prevention of psychiatric decompensation. Untreated psychosis places both the patient and the fetus at significant risk. Effective treatment with an antipsychotic agent may enable the mother to carry out necessary self-care and prenatal care.[257] Ideally, treatment decisions should be made as part of a multidisciplinary team consisting of the patient, mental health provider, obstetrician, primary care provider, and pediatrician. General guidelines on treatment during pregnancy recommend[257]:



Stage 1: First Episode Psychosis
SGA[a,b,d] or FGA[c]
Stage 2:
SGA[a-d] or FGA[a-d] or clozapine[a]
Stage 3: Treatment Resistant Schizophrenia
Clozapine[a-d]
Stage 4:
Clozapine + FGA or SGA or ECT[a,c,d]
Stage 5:
FGA or SGA[c]
Stage 6:
Combination Therapy (SGA + FGA, FGA or SGA + ECT, FGA or SGA + mood stabilizer)[c]
Partial or Non-response to Treatment

The International Psychopharmacology Algorithm Project website. http://www.ipap.org/schiz/. Updated March 27, 2006. Accessed February 1, 2016.])

1. Utilizing antipsychotic monotherapy at an adequate dose versus combination therapy
2. Avoiding medication switching to minimize exposure to the fetus and risk of psychiatric relapse
3. Selecting appropriate treatment based on history of efficacy, prior exposure during pregnancy, and available evidence on safety

4. Choosing medications with fewer metabolites, fewer interactions, and higher protein binding are generally preferred

Data on the safety of antipsychotics during pregnancy are limited due to ethical barriers to conducting well-designed, prospective controlled trials. There is inconclusive evidence linking fetal exposure to antipsychotics and major congenital malformations, perinatal mortality, high birth weight (SGAs), and low birth weight (FGAs).[256] A large-scale prospective national pregnancy registry for atypicals antipsychotics reported three major fetal malformations in a cohort of 214 patients with first-trimester exposure to SGAs. The control group, which included 89 live births, had one major malformation. This translates to an OR of 1.25 (95% CI = 0.13–12.19) between exposed and unexposed infants. Although ongoing data collection is still underway, these results suggest SGA exposure would be unlikely to increase the risk of major malformations higher than 10-fold of that observed in control groups or the general population.[258] In 2011, the FDA implemented safety labeling changes concerning the use of antipsychotic agents during the third trimester of pregnancy. They reported a risk that newborns may experience withdrawal symptoms or EPS; however, many cases were confounded by comorbid substance use and concomitant psychotropic medications. Symptoms usually resolved within hours-days without intervention; however, some may require prolonged hospitalization.[259]

CASE 85-1, QUESTION 34: Several months later, the clinic receives word from J.J.'s primary care provider that J.J. is pregnant, as confirmed by blood test. J.J. is still receiving clozapine and is fairly stable psychiatrically on the medication, even working part-time in a supermarket. J.J. does not want to lose the baby, but is worried about the effect of being on medication despite knowing it is what is keeping her stable. Should J.J. be continued on clozapine, and what are the risks to her baby if she does or does not?

Treatment of schizophrenia with antipsychotics during pregnancy must be considered carefully. As J.J. is currently stable and functional while taking clozapine, there is a significant risk of relapse if she stops the medication. During this relapse, if she were to engage in high-risk behaviors, it could be quite dangerous to both her and her baby. Maintaining stability is of great importance, as if J.J. can take care of herself appropriately it is more likely she will also take care of her fetus simultaneously. However, antipsychotics do carry risks of teratogenicity, and J.J. should be counseled on these risks. Clozapine is rated as pregnancy category B by the US FDA, which is better than most antipsychotics but still with some risk involved. The decision to maintain J.J. on clozapine during her pregnancy should be made by her, her psychiatrist, obstetrician, and other care providers to determine whether continuation of clozapine, and presumptive stability of her illness, is appropriate.

First-Episode Psychosis and Early-Onset Schizophrenia

Child and adolescent patients presenting with early psychosis are exquisitely sensitive to EPS and metabolic adverse effects of antipsychotics.[260,261] In general, symptoms of first-episode psychosis (FEP) respond to lower antipsychotic dosages. Therefore, the minimum effective dose should be utilized to minimize adverse effect burden. The question of which interventions are appropriate to initiate and when is complicated. Multiple studies support the effectiveness of antipsychotics in the treatment of early psychosis.[262–265] However, the treatment of prodromal symptoms is an area of debate. Prompt recognition of prodromal symptoms and patients with psychosis risk syndrome is crucial. Features associated with greater rates of conversion to psychosis in patients at ultra-high risk of psychosis include: genetic risk for schizophrenia, high levels of unusual thought content, high levels of suspicion and paranoia, social impairment, and history of substance use.[266] There is emerging evidence to support early initiation of omega-3 fatty acids or antidepressants to reduce rates of conversion to psychosis in high-risk patients.[261,267,268] Early engagement with appropriate comprehensive, multidisciplinary clinics results in improved quality of life and psychopathology, greater involvement in educational and vocational pursuits, and increased treatment follow-up.[269,270] Reduction of the duration of untreated psychosis leads to improved long-term prognosis and greater likelihood of achieving symptom remission.[44,271,272] Neurocognitive impairment is also a key predictor of functional outcome in early schizophrenia. Unfortunately, available pharmacologic options have limited impact on neurocognition.[273] Cognitive enhancement therapy, in conjunction with antipsychotic medication, can lead to durable improvements in neurocognitive functioning, social adjustment, and employment for patients with early psychosis.[274,275]

After achieving initial remission, guidelines recommend continued maintenance treatment with an antipsychotic for at least 1 year.[44,102,255] Studies of medication discontinuation demonstrated 5 year relapse rates from 80%.[276] However, cautious dose reduction strategies as soon as 6 months after remission may improve long-term functional recovery. Wunderink and colleagues conducted a seven-year follow-up study of a two-year open RCT comparing maintenance therapy (MT) versus dose reduction/discontinuation (DR) after 6-month remission of FEP. In the initial RCT, 128 patients were randomized to MT or DR and followed for 18 months. The MT group showed benefit in short-term relapse rates over the DR group.[277] However, the DR group had approximately twice the recovery rate of patients in the MT group (40.4% vs. 17.6%, respectively) at the seven-year follow-up and there were no significant differences in long-term relapse rates.[278] A limitation to the generalizability of the study is the population who agreed to enrollment in the initial phase had a higher level of functioning, greater adherence, and was easier to engage. These findings demonstrate the potential impact of limiting total antipsychotic burden on functional recovery rates of patients with remitted FEP. The lower adverse effect burden from minimizing the antipsychotic dose allows for improved social engagement, improved therapeutic alliance, and lower risk of self-discontinuation due to tolerability issues. Functional recovery is the key treatment goal in the early course of schizophrenia. Getting patients engaged in treatment early on in the illness course, utilizing the lowest clinically effective dosages of

---

antipsychotics, and providing psychoeducation can mean the difference in a patient recovering from a psychotic episode and completing college, returning to work, or engaging in meaningful social outlets.

CASE 85-1, QUESTION 35: J.J. gives birth to a son, R.J., who has a normal delivery. Over the course of time, R.J.'s pediatrician notes he is not socializing like other children, especially into adolescence. He is now age 15 and tends to isolate himself, does not have many peer friends, and recently has started performing poorly in school. His teachers have asked the pediatrician to evaluate R.J. for potential attention deficit hyperactivity disorder (ADHD) as he is often found not paying attention in class. J.J. also tells the pediatrician that she thinks R.J. still has "imaginary friends" as she often sees him alone in his room talking to people who are not there. What is potentially happening with R.J. and how should he be treated at this time?

R.J. is at higher risk for and potentially showing symptoms of early-onset schizophrenia. His lack of socialization and his isolation could be symptoms of the prodromal phase of schizophrenia. His "imaginary friends" could be R.J. responding to auditory and/or visual hallucinations; imaginary friends are not usually seen into adolescence. If these are hallucinations, this could also explain his lack of attention in school, which would not be ADHD. Considering his mother has schizophrenia, there is a definite genetic link to the illness in R.J. Once R.J. is evaluated for schizophrenia, it may be appropriate to initiate an antipsychotic at that time. If so, he should be started on an agent with minimal adverse effect burden at a minimal dose to control his symptoms. He should be evaluated regularly for possible medication discontinuation if warranted, but may require more long-term treatment depending upon his response and prognosis.

Depressive Disorders

Michael C. Angelini

CORE PRINCIPLES

		CHAPTER CASES
1	Depression is a common and often chronic disorder that may manifest at any time in one's life. Diagnostic criteria for major depression include a minimum of five symptoms persisting for at least 2 weeks. One of these symptoms must be either depressed mood or anhedonia. Suicidal ideation should be assessed in all patients.	**Case 86-1 (Question 1), Table 86-4**
2	A variety of treatment modalities are available for the management of depression. These include prescription medications, psychotherapy, and somatic treatments. Prescription medications and/or psychotherapy are indicated for depressive symptoms that are moderate to severe in nature, whereas somatic treatments are for severe refractory cases.	**Case 86-1 (Question 2), Case 86-2 (Questions 1, 2), Case 86-3 (Question 2)**
3	All of the prescription medications that are currently available are equally effective and possess the same delayed onset of therapeutic effects. Selection of an antidepressant is based on many factors, including previous response to medication, age, reproduction status, and both medical and psychiatric comorbidities.	**Case 86-1 (Questions 2, 4), Case 86-2 (Question 2) Case 86-4 (Question 1), Table 86-6**
4	SSRIs are regarded as the initial treatment of choice for most depressed patients. They are inexpensive and effective for comorbid anxiety conditions, and possess a lower side effect burden than other antidepressants overall. Side effects are generally mild and transient.	**Case 86-1 (Question 2), Case 86-2 (Question 1)**
5	Educating the patient regarding side effects, how to monitor for efficacy, and the duration of treatment is important action for successful treatment.	**Case 86-1 (Question 3), Case 86-3 (Question 3), Table 86-10**
6	The goal of antidepressant treatment is remission of symptoms. Once remission is achieved, the general recommendation is to continue the effective antidepressant regimen for a minimum of 6 months.	**Case 86-1 (Question 3), Table 86-10**
7	Because only half of depressed patients will achieve remission with the first antidepressant selected, clinicians should have a comprehensive understanding of the role many antidepressants may have in optimizing outcomes. Clinicians should be familiar with switching antidepressants in patients with an incomplete response, and the merits of augmentation strategies.	**Case 86-2 (Questions 1–3)**
8	Untreated depression in children under 18 has a significant risk of	**Case 86-3 (Questions 1, 2)**

	suicide. Treatment consists of talking therapy and specific antidepressants, which is different than the broad options available to adults.	
9	Depression and chronic pain are commonly comorbid, and pharmacologic treatment that addresses both is recommended. This makes the SNRI class of antidepressants preferred.	**Case 86-4 (Question 1)**

INTRODUCTION

In general, depressive disorders are enormous health concerns that are often misdiagnosed or undertreated. The physical and social dysfunction associated with depression is profound and is believed to outweigh many other chronic medical conditions, including hypertension, diabetes, and arthritis.[1] The Medical Outcomes Study determined that the degree of impairment in depressed individuals is comparable to that seen in patients with chronic heart disease.[2] The financial ramifications of depression are tremendous and place an overwhelming burden on our society. In 2000, the estimated cost of depression in the United States was $83.1 billion annually, with most of these costs ($51.5 billion) attributed to lost productivity and absenteeism in the workplace.[1,3]

Epidemiology

Since World War II, the lifetime incidence of depression has been rising steadily in studied populations. The annual incidence of all mood disorders is approximately 10% in the adult population, and 1 in 15 adults (6.7%) will suffer from an episode of major depression during any 12-month period.[4] Various studies from Europe and the United States have estimated the 1 year and lifetime prevalence to be 4.1% and 6.7%, respectively.[5] Although the incidence of depression is remarkably similar across various races and ethnic groups, the illness may be slightly more common in lower socioeconomic classes and women having double the incidence than men.[1,5]

The onset of depression occurs most commonly in the late 20s, but there is a wide range, and the first episode may actually present at any age. Genetic factors appear to play a major role in the cause of depression. The offspring of depressed individuals are 2.7 times more likely to have depression if one parent is afflicted, and 3.0 times more likely if both parents suffer from depression.[6] Concordance rates for monozygotic (identical) twins range from 54% to 65%, whereas the corresponding rates in dizygotic (fraternal) twins range from 14% to 24%.[7] Genetic factors may also predispose individuals to an earlier onset of depression (younger than 30 years of age).[8] Additionally, there is clear evidence that depression may occur as a result of stressful events (i.e., environmental factors) in one's life. These factors include a difficult childhood, physical or verbal abuse, pervasive low self-esteem, death of a loved one, loss of a job, and the end of a serious relationship. Acute depressive episodes are often attributed to a combination of environmental and genetic factors. For instance, individuals carrying a genetic predisposition to mood disorders may undergo a stressful experience that ultimately triggers the manifestation of depressive symptomatology. Depression may also occur spontaneously among people who appear to lack any obvious genetic or environmental predisposition.

Diagnosis and Classification

When assessing a person for depression, it is important to recognize the level of impairment due to the symptoms. Just as with all biologic systems, the body can function well within a particular range (e.g., serum potassium or BP). Mood is not different; as long as the depressive symptoms are not prolonged or impairing, there would be no reason to aggressively treat. Once the depression is severe enough to impact functioning or induce harm, it requires treatment.

Major depressive disorder (MDD) may manifest as a single episode, but it is more commonly a series of recurrent events. Thus, in most patients, depression is a chronic illness.[5] The frequency of recurrent episodes is highly variable, with some people experiencing discrete episodes separated by many years of relatively normal mood (euthymia), and others experiencing residual symptoms between episodes that may never completely remit. The risk of future episodes appears to increase disproportionately with the chronicity of the illness. For instance, after the first episode there is a 50% likelihood of a second episode. After the second, there is a 70% chance of a third, and with the third episode comes nearly a 90% incidence of a fourth.

Table 86-1

Classification of Depressive Disorders

1. Major depressive disorder
2. Persistent depressive disorder
3. Disruptive mood dysregulation disorder
4. Premenstrual dysphoric disorder
5. Substance/medication-induced depressive disorder
6. Depressive disorder due to another medical condition
7. Other specified depressive disorder
8. Unspecified depressive disorder

Adapted with permission from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders. 5th ed. Washington, DC: American Psychiatric Association; 2013.

The Diagnostic and Statistical Manual 5th edition (DSM-5) describes different types of depressed states. These include disruptive mood dysregulation disorder, MDD, persistent depressive disorder, premenstrual dysphoric disorder, substance/medication-induced depressive disorder, depressive disorder due to another medical condition, other specified depressive disorder, and unspecified depressive disorder (Table 86-1).[9] The different types of depressive disorders may then be subclassified using cross-sectional symptom features, or specifiers. For example, the phrase "with anxious distress" which infers that there are anxiety symptoms such as worry and feeling keyed up. The term "with mixed features" infers that there are manic or hypomanic symptoms. The term "with melancholic features" is used when patients possess primary neurovegetative symptoms, early morning awakening, marked psychomotor agitation or retardation, and significant anorexia or weight loss. Melancholia is often a more severe form of depression, and it often lacks apparent environmental triggers.[9,10] It may also be less likely than other forms of depression to remit spontaneously. The phrase "with atypical features" is used when depressive symptoms include weight gain, hypersomnia, leaden paralysis, or rejection sensitivity. When hallucinations or delusions occur in patients who are primarily depressed, the phrase "with mood congruent or mood incongruent psychotic features" is applicable to the mood disorder. Other diagnostic specifiers used in DSM-5 include "with catatonia," and "with peripartum onset," and "with seasonal pattern."

Persistent depressive disorder is a type of depressive illness characterized by fewer symptoms and less intensity than major depression, but the course is much more chronic with symptoms being present most of the time for at least 2 years. In practice, the detection of persistent depressive disorder may be difficult to make because patients often do not seek treatment because they are still functional (e.g., go to school, work, care for children) but they have significant morbidity. They will have less satisfaction with work and will get fewer promotions and poor raises. The treatment for persistent depressive disorder has traditionally focused on psychotherapy, but evidence suggests that antidepressant medications may actually be more effective.[11]

Differential Diagnosis

Symptoms of depression may be induced or exacerbated by numerous medical illnesses or medications (Tables 86-2 and 86-3).[1,5,10] Consequently, DSM-5 specifies that whenever an medical event is temporally related to the onset of depressive symptoms, the patient does not fit the criteria for major depression, even if all other criteria are met.[9] The rationale for this stipulation is that if the medical illness is successfully treated or the offending agent is discontinued, the depressive illness would spontaneously resolve, eliminating the need for psychiatric intervention. Although lists of medical illnesses or medications are helpful, the clinician should be aware that the actual evidence demonstrating an association between depression and specific organic causes is limited. If a medication or condition is suspected of causing depression, the chronologic association should be investigated rigorously before other action is taken. Additionally, a patient with a medical illness such as a hormonal abnormality may have depressive symptoms from the condition but can additionally have concomitant MDD. Treating the medical condition will likely lessen the severity but the MDD will still have to be treated as well.[1,5,10]

Clinical Presentation

For a diagnosis of MDD to be made, symptoms must be present for at least 2 weeks and must not be precipitated or influenced by a medical illness or medication (according to DSM-5 criteria). Individuals must possess at least five symptoms, one of which is either depressed mood or anhedonia (diminished interest or pleasure in activities). The other seven symptoms are as follows:

1. Change in appetite or significant weight loss or gain
2. insomnia or hypersomnia
3. Psychomotor agitation or retardation
4. Fatigue or loss of energy
5. Feelings of worthlessness or inappropriate guilt
6. Poor concentration (or difficulty making decisions)
7. Recurrent thoughts of death or suicidal

The diagnostic criteria also state that the mood disturbance must cause marked distress or result in clinically significant impairment of social or occupational functioning. Additionally, the symptoms cannot be due to a medical or organic illness (Table 86-4).

Pathophysiology

The monoamine hypothesis proposed that decreased synaptic concentrations of norepinephrine (NE) and/or serotonin (5-HT) caused depression. The NE depletion theory was originally based on the observation that reserpine, which depleted catecholamine stores in the central nervous system (CNS), was capable of causing depression.[12,13] This theory evolved into the permissive hypothesis, which emphasized a greater role for serotonin in promoting or “permitting” a decline in NE function. Specifically, this hypothesis suggests that low concentrations of serotonin or NE in the CNS precipitated depressive symptoms. Studies have shown that a 5-HT synthesis deficiency is correlated with depression. This has been shown in both persons genetically unable to produce 5-HT and those who have depleted precursors of 5-HT.[14,15] Selective serotonin reuptake inhibitor (SSRI) and serotonin and norepinephrine reuptake inhibitor (SNRI) antidepressants, which functionally include the tricyclic antidepressants (TCAs), are believed to relieve depression by inhibiting the reuptake of serotonin alone or serotonin and NE from the synapse up into the neuron, effectively increasing neurotransmitter concentrations in the synaptic cleft.[16,17] Mirtazapine and MAOIs work via different mechanisms, but also increase 5-HT and NE (and DA for the MAOIs).[16,17]

Table 86-4

Diagnostic Criteria for Depressive Episode

- At least five of the following symptoms have been present during the same 2-week period and represent a change from previous functioning. One of the symptoms must be either depressed mood or loss of interest/pleasure.
  - Depressed mood most of the day, nearly every day
  - Loss of interest in pleasurable activities most of the day, nearly every day
  - Significant change in weight or appetite (increase or decrease) when not dieting
  - Insomnia or hypersomnia nearly every day
  - Fatigue or loss of energy nearly every day
  - Diminished ability to think or concentrate, or indecisiveness
  - Feelings of worthlessness or excessive or inappropriate guilt nearly every day
  - Psychomotor agitation or retardation nearly every day
  - Recurrent thoughts of death or suicidal ideation
- Symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- Symptoms are not caused by an underlying medical condition or substance (e.g., medications or recreational drugs).
- For the diagnosis of major depressive disorder (MDD), this episode must not be part of schizophrenia, schizoaffective, delusional, or bipolar disorder.

Adapted with permission from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders. 5th ed. Washington, DC: American Psychiatric Association; 2013.

Depression has been associated with changes in presynaptic and postsynaptic receptor densities (or sensitivities) that have been described as being downregulated or desensitized.[18] Changes include a decrease in postsynaptic α-adrenergic receptor sensitivity, along with alterations in the sensitivities of the α-adrenergic, dopaminergic (D_2), and serotonin receptor subtypes (5-HT_{1A} and $5HT_{2A}$). For example, SSRIs can increase the efficiency of serotonergic neurotransmission acutely (through reuptake blockade), but their therapeutic effects are linked temporally with increased release of serotonin through downregulation of presynaptic autoreceptors (5-HT_{1A}).[19] This downstream impact explains why there is a delay in maximal efficacy seen with all antidepressants.[14,15]

As our understanding of neurobiology increases, it has been found that other neurotransmitter systems can impact mood and this has resulted in research for non-5-HT direct-effect medications to supplement or replace the monoamine effecting antidepressants. Such mechanisms include blockade of substance P and antagonism of corticotropin-releasing factor or corticosteroid receptors.[20–23]

Neuroendocrine Findings

Along with dysregulated neurotransmitter systems, neuroendocrine abnormalities may contribute to the development of depression. Depressed patients often have abnormal thyroid function tests (including low triiodothyronine [T_3] and/or thyroxine [T_4] levels).[24] They also may exhibit an abnormal response to challenge with thyroid-releasing hormone, consisting of a blunted or exaggerated thyroid-stimulating hormone response.[25] Clinical hypothyroidism can also induce depressive symptoms, and thyroid supplementation can reverse this pathology, suggesting an indirect association between mood disorders and thyroid homeostasis.[26] The hypothalamic–pituitary–adrenal (HPA) axis may also influence the manifestation of depression, with a relative hyperactivity of this system commonly reported in depressed individuals.[27,28] Pituitary and adrenal glands are often enlarged in depressed patients, and concentrations of corticotropin-releasing factor are often elevated during depressive episodes and decline with the administration of antidepressant medications or electroconvulsive therapy (ECT).[22,29] Exogenous administration of corticotropin-releasing factor has elicited classic symptoms of depression in laboratory animals (including decreased appetite, anxiety, insomnia, and decreased libido).[23] In humans, medications that block postsynaptic corticosteroid receptors have also displayed antidepressant properties.[23,30,31] Interestingly, serotonin has been recognized as a strong influence on the HPA axis (and vice versa). Activation of the postsynaptic serotonin receptors (5-HT_2) along the hypothalamic paraventricular nucleus can stimulate corticotropin-releasing hormone–secreting neurons. Loss of hippocampal volume in major depression leads to increased levels of circulating glucocorticoids, which leads to neuronal apoptosis.[32] Hypercortisolemia due to chronic stimulation of the HPA axis has been implicated in potentially reducing gray matter loss in humans. It should be noted that the relationship between hippocampal volume and depression is not consistently observed and that various factors may affect these findings.[33] Corticosteroids can also modulate serotonin synthesis, metabolism, and reuptake.[22] However, the data in this area are inconsistent because different medications will have differing effects on cortisol despite being effective as well as depressive subtypes showing different effects on cortisol.[34,35] Increased inflammatory cytokines are seen in prospective and postmortem studies of depressed patients but, again, is not consistent.[27,36]

Genetic Studies

Over the last few years, significant scientific advances have been made in genetics and pharmacogenomics. Several genes have been implicated in predictive response or adverse effects to antidepressants. Pharmacodynamic targets have focused on serotonin transporters (5-HTTLPR), tryptophan hydroxylase enzymes 1 and 2 (TPH1 and TPH2), 5-HT_{1A} and 5-HT_{2A} receptors, brain-derived neurotrophic factor (BDNF), G-protein β-3 subunit (GNB3), and monoamine oxidase enzymes and p-glycoprotein; pharmacokinetic targets have been focused on polymorphic variations in CYP1A2, CYP2C19, CYP2D6, and CYP3A4 enzymes.[37–39] Variations in the serotonin transporter SLC6A4 gene have been associated with remission and response rate in a meta-analysis of 1,435 patients.[38] Researchers found that patients with the ss genotype are less likely to reach remission during SSRI treatment and take longer to achieve 50% symptom improvement compared to those with the ll genotype. A recent review stated the genes SLC6A4, HTR2A, BDNF, GNB3, FKBP5, ABCB1, and cytochrome P450 genes (CYP2D6 and CYP2C19) as being the best correlated with depression.[40] A major challenge with pharmacogenomic studies lies in the difficulty of defining unambiguous drug response phenotypes in complex diseases, such as depression. Most likely there are multiple genes that are involved in disease phenotype, drug response, and toxicity. Gene–environment interactions undoubtedly also play a role in the determination of these phenotypes.

Imaging Studies

Imaging studies (including computed tomography, magnetic resonance imaging, positron emission tomography, and single-photon emission computed tomography) suggest that patients with depression have regional brain dysfunction, most often affecting the limbic structures and prefrontal cortex. Alterations in cerebral blood flow and/or metabolism in the frontal–temporal cortex and caudate nucleus are associated with common depressive symptoms such as dysphoria, anhedonia, hopelessness, and flat affect.[41] Increased firing of the amygdala in the left hemisphere has been linked in positron emission tomography studies with the future development of depression.[42] Because subtypes of depression have been linked to different regional dysfunctions, a network hypothesis began to emerge that may lead to improvements in depression diagnosis and targeted treatments.[43] There is also seemingly increased hippocampal loss that is consistent with severity and duration of illness.[44]

Patient Assessment Tools

Behavioral rating scales have been used for many years in drug efficacy studies and are widely advocated for routine use in the clinical arena today. Rating scales are helpful in assessing the severity of mental illness, quantifying changes in target symptoms, and determining treatment efficacy, but they are not diagnostic. Rating scales can vary in length, content, and format, and can be completed by providers, patients, researchers, family members, or conservators. Numerous depression scales have been developed, including the Hamilton Rating Scale for Depression (HAM-D_{17} or HAM-D_{21}), the Hospital Anxiety and Depression Scale (HADS), the Beck Depression Inventory (BDI), the Montgomery-Åsberg Depression Rating Scale

(MADRS), the Center for Epidemiological Studies Depression (CES-D) Scale, the Patient Health Questionnaire (PHQ-9), and the Quick Inventory of Depressive Symptoms (QIDS$_{16}$ or QIDS$_{30}$) (Table 86-5).[45–51] Because 30% to 50% of cases are not detected in primary care, enhancing education of the clinicians in this area has shown some benefit. Generally, a two-step process of screening with a simple questionnaire, such as the PHQ-9 or the HADS, and then a more thorough evaluation if the screening results in a positive score are the recommended methods of detecting depression severe enough to require treatment.[5,52]

Table 86-5

Comparison of Selected Depression Rating Scales

Instrument	Minimal	Mild	Moderate	Severe
Hamilton (HAM-D)—17 item (clinician rated)	<8	8–15	16–27	>27
Beck Depression Inventory (BDI)				
BDI (clinician rated)	<10	10–16	17–29	>29
BDI (patient rated)	<10	10–15	16–23	>23
Quick Inventory for Depressive Symptoms (QIDS)				
QIDS-C$_{16}$ (clinician rated)	<6	6–10	11–15	>15
QIDS-SR$_{16}$ (patient rated)	<6	6–10	11–15	>15
Patient Health Questionnaire (PHQ) (patient rated)	<10	11–14	15–19	>19
Montgomery-Åsberg Depression Rating Scale (MADRS) (clinician rated)	<7	7–19	20–34	>34

Nondrug Therapies for Depression

PSYCHOTHERAPY

For the treatment of mild-to-moderate depression, psychotherapy has proved to be comparable to pharmacologic intervention and may be preferred by some patients. There are many types of psychotherapy, and experts suggest that cognitive behavioral therapy (CBT), behavioral activation (BA), and interpersonal psychotherapy (IPT) are effective with CBT being preferred for monotherapy.[5] For the acute treatment of severe depression, antidepressants appear to be more effective than psychotherapy alone and have a more rapid onset of therapeutic action.[5,26] The beneficial effects of psychotherapy, however, may persist longer than medication-related benefits after the interventions have been formally discontinued. In addition, psychotherapy may be particularly beneficial for preventing relapse among patients who previously demonstrated a therapeutic response to antidepressants.[53] Overall, the combination of treatments is superior to either intervention alone.[5,10]

SOMATIC INTERVENTIONS

ECT is a safe, rapid-acting, and highly effective therapeutic intervention. ECT was enormously popular during the 1940s and 1950s and was used without discretion to treat a wide variety of psychiatric conditions. This practice waned with the advent of effective psychotropic medications, and with the accumulation of case reports describing fractures and severe cognitive impairment in treated patients. Since the 1950s, the ECT procedure has undergone considerable transformation and refinement.[54] Adjunctive medications are now routinely administered to prevent adverse effects and reduce morbidity (e.g., a short-acting barbiturate for general anesthesia, an anticholinergic agent to prevent bradycardia and to dry excessive airway secretions, succinylcholine to prevent fractures from tonic–clonic contractions). The electric stimulus itself is no longer applied in one steady current but now consists of a series of brief pulses that have been shown to decrease the severity of postictal headaches and memory impairment.

Fundamentally, ECT features the induction of generalized seizures through an electric current delivered by bilateral or unilateral electrode placement. Medications that raise the seizure threshold or promote cognitive impairment (lithium) should be discontinued before the procedure although this is not always necessary. Adverse effects are generally minimal and consist mainly of transient anterograde amnesia (i.e., difficulty remembering events around the time of the procedure), retrograde amnesia, confusion, headaches, and muscle aches. Cardiovascular effects (e.g., ventricular arrhythmias, myocardial infarction [MI]) are the most ominous sequelae, but these events are extremely rare.[54]

ECT is recommended for patients with treatment-resistant depression, severe vegetative depression, psychotic depression, and severe depression in pregnancy. Overall response rates are impressive, ranging from 70% to 90%, and ECT has the distinct advantage of inducing a therapeutic response within the first week or two of treatments.[54–56] The recommended frequency of ECT treatments is variable. Most institutions have used three sessions weekly to induce a therapeutic response acutely, although evidence suggests that twice-weekly sessions are better tolerated and more cost-effective.[57] The frequency of treatments thereafter (i.e., maintenance therapy) is recommended that ECT be administered weekly for 1 month and less frequently thereafter may be as effective as aggressive pharmacotherapy in preventing relapse.[58]

Other somatic interventions have also been used successfully to treat depression. Repetitive transcranial magnetic stimulation (rTMS) is a noninvasive procedure involving the application of an electrical magnetic stimulus across the scalp, which ultimately generates an electrical field in the cerebral cortex.[59,60] Unlike ECT, rTMS does not generate an actual seizure, and it is very well tolerated, with common side effects consisting of transient scalp discomfort and headaches. Preliminary investigations successfully used repetitive high-frequency techniques in depressed subjects, and imaging studies have shown functional improvements consistent with antidepressant properties. However, not all studies have shown efficacy, and overall results show only a slight benefit for depression or treatment refractory depression.[56,61,62] In 2008, the US Food and Drug Administration (FDA) decided to allow the marketing of TMS for patients who failed a minimum of one prior antidepressant trial.

Vagus nerve stimulation involves the surgical implantation of an electrical device in the subcutaneous tissue below the clavicle, which sends an impulse along the left vagal nerve into the cerebral cortex. Setting adjustments are through a telemetric wand.[56,63] It is currently FDA-approved for the management of

---

treatment-resistant depression although its effect takes time and cannot be considered an acute therapy. Implantation of the device is an invasive procedure with standard risks associated with this type of surgery. However, long-term safety has been shown in both epilepsy and depression studies. It may be useful when combined with medication treatment.[56]

Light therapy or phototherapy is particularly effective for relieving the irritability and malaise associated with seasonal affective disorder, a milder form of depression that has been attributed to decreases in natural sunlight found with seasonal variation.[10,64] Phototherapy is administered in the form of a light box delivering 1,500 to 10,000 lux for a period of 1 to 2 hours daily. It is extremely well tolerated.

LIFESTYLE ADJUSTMENTS

Any therapeutic approach to mood disorders should seek to reverse unhealthy or destructive lifestyle habits and promote other activities that may relieve stress and facilitate well-being. Alcohol and illicit drug use should be minimized (if not prohibited) in patients suffering from depressive disorders. Sleep habits should be evaluated and improved to ensure optimal rest. Dietary factors should be modified to promote diverse, balanced, and nutritional eating habits.

Increased physical activity and sustained cardiovascular exertion can impart a variety of health benefits, including improvement in depressive symptoms.[5] Although investigations examining the effectiveness of exercise for depression have met with mixed results, exercise can regulate appetite, improve sleep patterns, increase energy, enhance self-esteem, and promote a return to euthymic status.[65] Exercise has been shown to increase circulating concentrations of serotonin in the periphery and enhance neurogenesis in the hippocampus.[66] Other activities may also serve to relieve stress and help patients acquire insights into their emotional well-being. These pursuits can range from daily journal writing (journaling), meditation, yoga, and Tai chi. Classes in mindfulness-based meditation, in particular, are offered at many medical centers, and the health benefits of this approach have been demonstrated in a wide range of medical conditions including cancer, chronic pain syndromes, and human immunodeficiency virus (HIV) illness.[67]

MAJOR DEPRESSIVE DISORDER

CASE 86-1

QUESTION 1: A.R. is a 25-year-old female in graduate school who presents to the student health clinic for a routine physical examination. During her visit, A.R. states, "I've been feeling pretty down lately and just want to give up." Her physical examination is unremarkable, and all laboratory tests (complete blood count with differential, chemistry panel, and thyroid function tests) are within normal limits. A human chorionic gonadotropin test is negative. Her medical history is noncontributory, takes no medication, uses a daily multivitamin, and denies drinking alcohol, smoking cigarettes, or using illicit substances.

Diagnosis

When asked, A.R. states that she has had increasing periods of depressed mood during the past few months and often finds herself crying in the morning for no particular reason. She reports that she has no interest in her old hobbies (playing the piano, mountain biking, gardening). During the past 6 months, her appetite has decreased, and she has lost 15 pounds. She feels overwhelmed about all of her academic work and job and has difficulty sleeping, often waking in the middle of the night and being unable to fall back asleep. She has no energy during the day and finds it difficult to concentrate or make decisions. This is clearly impacting her ability to finish her graduate work as she is falling behind and has been getting extensions for her project due dates.

On examination, A.R. is an appropriately dressed woman who appears sad but who is alert, coherent, and logical. Her affect is constricted, apprehensive, and sad. Mood is depressed, and she admits having vague suicidal ideation but she has no specific plans. She is oriented to person, place, and time, but shows some recent memory deficits. Her intelligence is estimated to be above average. Concentration and abstractions (e.g., "don't cry over spilled milk," "a rolling stone gathers no moss") are satisfactory. She denies hearing voices or other hallucinations. She denies any symptoms of mania such as increased periods of energy, rapid speech, and racing thoughts (See Chapter 87, Bipolar Disorders). She has good insight and judgment into her illness. A.R. is asked to complete the PHQ-9 and has a total score of 15 with five different questions scoring 2 or more and as well as question one and two scoring 2 (i.e., moderate-to-severe symptoms). After reviewing the PHQ-9 results, a more in-depth interview is conducted and A.R. is diagnosed as having MDD. What nondrug options have shown efficacy?

From A.R.'s history, she appears to be exhibiting a dysphoric or depressed mood as well as anhedonia (lack of interest in hobbies or pleasurable activities). In addition, she demonstrates frequent episodes of crying, decreased appetite (with an unintentional 15-pound weight loss), poor concentration, low energy, suicidal ideation, worthlessness, and inappropriate guilt. Her mental status examination is consistent with these target symptoms, revealing a constricted, sad affect (physical manifestation of inner emotional states), and frequent crying episodes during the interview.

Based on the DSM-5 criteria (Table 86-4), A.R. has MDD. During the past 2 weeks, she has consistently exhibited at least five of the associated symptoms, one of which is depression or anhedonia. It does not appear that her symptoms are the result of any medical condition, medication, thought disorder, or uncomplicated bereavement. These are impacting functioning because she is not able to complete her school work assignments.

Psychotherapy has been shown to have beneficial effects on mild-to-moderate depression. Studies have also shown that combined with medication the beneficial effects are greater than either alone. ECT is an effective somatic treatment but typically reserved for more refractory cases. rTMS is currently being studied but has not been standardized yet. Lifestyle modifications such as exercise generally have benefit, but typically are not strong enough on their own to treat clinically significant depressed symptoms.

DRUG MANAGEMENT

Drug Selection: General Considerations

CASE 86-1, QUESTION 2: A.R. agrees to a therapeutic trial of an antidepressant. What are the drug options available for A.R.'s depressive symptoms? What considerations should be made when selecting antidepressant therapy?

In randomized, controlled trials (RCTs) of antidepressants, a therapeutic response is usually apparent in 60% to 70% of subjects receiving active medication (therapeutic response is defined as a ≥50% decline in depression rating scale score).[5,10]

Antidepressants can be divided into different categories:

1. Selective serotonin reuptake inhibitors (SSRIs)
2. Serotonin norepinephrine reuptake inhibitors (SNRIs)
3. Tricyclic antidepressants (TCAs)

4. Miscellaneous antidepressants (e.g., trazodone, nefazodone, mirtazapine, bupropion)
5. Monoamine oxidase inhibitors (MAOIs)
6. Serotonin reuptake inhibitor and receptor modulators (the newest group)

When comparing the impact of antidepressants on changes in depressive symptoms, all antidepressants are considered equal, regardless of class. It is possible that dual-acting antidepressants (SNRIs and TCAs) may be more effective in the severely depressed but this has not resulted in experts explicitly recommending them over other factors such as comorbid diseases, contraindications, or drug interactions (Tables 86-6 and 86-7)[5,10,26,68] Sertraline and escitalopram have the best efficacy to safety/tolerability ratio.[5,10,68,69] Thus, with no other factors influencing the selection of the medication, it may be easier to select either of these.

One of the first factors to consider is the patient's history of response to previous antidepressant drug therapy. If this history is unavailable (or the patient has never received an antidepressant before), the clinician should inquire about family history. If a first-degree relative had a successful course of antidepressant treatment with minimal adverse effects, that specific medication (or another from the same antidepressant class) would be a prudent choice for initial therapy. The potential impact of an antidepressant on concurrent medical conditions or disease states is often considered next. For example, certain antidepressants (e.g., TCA, paroxetine, mirtazapine) can cause significant weight gain and would not be desirable choices for obese patients, whereas bupropion should be avoided in patients with a history of seizures. Pharmacokinetic drug interactions will also help determine the preferred first-choice option. Among the SSRIs, fluoxetine and paroxetine have significant inhibitory effects on CYP450 2D6, whereas citalopram, escitalopram, sertraline, and fluvoxamine have minimally clinical inhibitory effects on 2D6. Fluvoxamine does have a strong impact on CYP1A1/2, and fluoxetine has a weak-to-moderate impact on 3A4 (Table 86-8).[70] Other important patient-specific factors to consider in the selection of an agent include safety in overdose, ease of administration (once-daily vs. divided doses), and necessity for dose titration, cost, and patient preference (Tables 86-6–86-9).[10]

Table 86-6

Factors to Consider in Selecting an Antidepressant

- History of prior response (personal or family member)
- Safety in overdose
- Adverse effect profiles
- Patient age
- Concurrent medical/psychiatric conditions
- Concurrent medications (e.g., potential for drug interactions)
- Convenience (e.g., minimal titration, once-daily dosing)

- Cost
- Patient preference

Table 86-7

Pharmacology of Antidepressant Medications

Medication	Serotonin	Norepinephrine	Dopamine	Bioavailability (Oral)	Protein Binding	Half-Life (hours) (Active Metabolite)
Selective Serotonin Reuptake Inhibitors						
Fluoxetine	+ + + +	0/+	0	80%	95%	24–72 (146)
Sertraline	+ + + +	0/+	+	>44%	95%	26 (66)
Paroxetine	+ + + +	+	0	64%	99%	24
Citalopram	+ + + +	0	0	80%	<80%	33
Escitalopram	+ + + +	0	0	80%	56%	27–32
Serotonin Norepinephrine Reuptake Inhibitors						
Venlafaxine	+ + + +	+ + +	0	92%	25%–29%	4 (10)
Desvenlafaxine	+ + +	+ + +	0	80%	30%	11 (0)
Duloxetine	+ + + +	+ + + +	0	50%	>90%	12 (8–17)
Levomilnacipran	+	+ + + +	0	92%	22%	12
Dopamine/Norepinephrine Reuptake Inhibitors

Treatment Expectations

A similar delayed pattern of therapeutic response has been observed with all antidepressant medications. Patients often begin to show signs of clinical response during the first 1 or 2 weeks of active treatment and maximum improvement may not be evident until weeks 6-8.[5,26,71] The pattern of patient response can also be generalized, with neurovegetative symptoms often the first to subside (e.g., altered sleep or appetite, decreased energy, excessive worrying and irritability). Cognitive symptoms are slower to respond, and 3 to 4 weeks or more may elapse before improvements are evident. These symptoms include excessive guilt or pessimism, poor concentration, hopelessness or sadness, and decreased libido.

Selective Serotonin Reuptake Inhibitors

ADVERSE EFFECTS

There is a delay in onset of full efficacy, but side effects will occur soon after starting the medication. Common side effects of SSRIs are related to the fact that despite their neurotransmitter specificity to increasing the amount of serotonin in the synapse there are at least 14 different serotonin receptors having different effects.[15] Distinct side effect profiles have emerged, consisting of gastrointestinal (GI) complaints, CNS disturbances, and sexual dysfunction.

All of these medications may induce nausea, but this tends to be a transient effect that diminishes after the first week of treatment. Typically, SSRI-induced nausea occurs 1 to 2 hours after oral administration. Nausea with SSRIs can be a local effect but is also mediated centrally through the extra serotonin-stimulating serotonin receptors (5-HT$_3$) that activate the chemoreceptor trigger zone.[72] SSRIs may also cause transient and bothersome increases in GI motility. This diarrhea is generally limited to the first few weeks of treatment and is also related to the extra serotonin-stimulating 5-HT$_3$ receptors along the GI tract. As with nausea, this diminishes in the first few weeks of treatment unless the dose is increased. In contrast, paroxetine possesses a relatively mild anti-muscarinic effect that can manifest as constipation, dry mouth, or urinary hesitancy. Although this effect is mild, paroxetine use is often discouraged in patients with preexisting constipation or those where any anticholinergic effects are to be avoided such as the elderly.

SSRIs can have myriad effects on the CNS, with disturbances in sleep being a primary concern. SSRIs can have significant but highly variable effects on sleep architecture. In sleep studies, SSRIs have been shown to increase sleep latency and decrease sleep efficiency, often resulting in morning sleepiness or malaise. Many patients also notice that their dreams become more vivid and memorable, which may be an undesirable experience. REM stage sleep may be prolonged, resulting in less fitful sleep.[73] It should be emphasized, however, that sleep may eventually improve once the antidepressant properties of the medications are apparent and baseline depressive symptoms are relieved (e.g., midnocturnal insomnia).

The deleterious effects of SSRI on sexual function can often lead to medication nonadherence.[74] The reported incidence of sexual dysfunction ranges from 1.9% to 75%, reflecting the difficulty in appropriately measuring this adverse event.[75] The actual incidence of SSRI-induced sexual dysfunction is approximately 30% to 50%, and it appears to be slightly more common in men, but the severity may be worse in women.[75] Delayed orgasm is the most common sexual complaint attributed to SSRIs or SNRIs, and should be distinguished from decreases in desire or libido, which are considered to be an aspect of the psychopathology of depression itself. This iatrogenic effect on orgasms has actually been used to clinical advantage in treating men by delaying premature ejaculation, but most patients find it undesirable.[75] All SSRIs are at risk for causing sexual dysfunction, because it is due to the increased serotonin-stimulating 5-HT$_{2c}$ receptors. Paroxetine has a higher rate than the others because it also inhibits nitric oxide synthase, reducing nitric oxide levels.[75] It also appears that this is a dose-dependent phenomenon, which may respond favorably to a decrease in daily dosage. Unlike the GI and CNS side effects reported with SSRIs, sexual dysfunction is not usually a transient adverse effect and must be addressed by clinicians if patients are to continue pharmacotherapy.

Table 86-9

Dosage Ranges of Commonly Prescribed Antidepressant Medications

Medication	Starting Dose (mg/day)	Usual Dosage (mg/day)
Selective Serotonin Reuptake Inhibitors		
Fluoxetine	20	20–60
Sertraline	50	50–200
Paroxetine	20	20–60
Paroxetine ER	12.5	25–75
Citalopram	20	20–60
Escitalopram	10	10–20
Serotonin Norepinephrine Reuptake Inhibitors		
Venlafaxine, IR	37.5	75–375
Venlafaxine, ER	37.5	75–375
Desvenlafaxine	50	50
Duloxetine	60	60–120
Levomilnacipran	20	40–120
Dopamine Reuptake Inhibitors		
Bupropion, IR	150	300–450
Bupropion, SR	150	300–400
Bupropion, ER	150	300–450
Tricyclic Antidepressants		
Imipramine	25–50	100–300
Desipramine	25–50	100–300
Amitriptyline	25–50	100–300
Nortriptyline	25	50–200
Others		
Mirtazapine	15	45
Nefazodone	50	150–300
Serotonin Reuptake Inhibitors and Receptor Modulators		
Vilazodone	10	20–40
Vortioxetine	10	20

A review of the clinical efficacy, safety and tolerability of the antidepressants vilazodone, levomilnacipran and vortioxetine. Expert Opin Pharmacother. 2014;15(17):2525–2542.

The detection and proper management of SSRI-induced sexual dysfunction can be one of the most important factors in ensuring medication adherence. Clinicians may be uncomfortable asking patients about their sexual activities and satisfaction, but the high incidence of this side effect (and low likelihood of patients volunteering this information) necessitates a thoughtful and direct approach. Some patients acknowledge sexual dysfunction but decide that improvements in mood and overall health outweigh limitations in sexual performance; however, others simply stop the medication if the side effect is never addressed.

It may be wise to advise patients that sexual function may change over time, depending on the type and etiology of sexual dysfunction experienced. Depression itself is associated with a decreased libido in 70% to 90% of untreated patients.[76] This symptom will most likely subside with a successful course of antidepressant treatment. Delayed ejaculation or anorgasmia, however, may be caused by SSRIs and SNRIs, often persisting and jeopardizing treatment.

Ordinarily, one of the first options in managing sexual dysfunction is to reduce the dosage, but this may induce a return in symptoms because increasing the dose initially was likely due to

lack of full effect. It is also possible to introduce drug holidays. Small open-label studies with short-acting SSRIs (e.g., paroxetine) suggested that if patients skipped their doses on Friday and Saturday, sexual function would return to normal on the weekends.[77,78] Although this method was reported to be successful, it may also promote nonadherence with medication and lead to increased risk of relapse and withdrawal symptoms and is therefore not recommended.

If the patient has had a therapeutic response to the antidepressant, the next option in this setting is to consider antidotes to SSRI-induced sexual dysfunction. One option is to add the antidepressant bupropion. Clinical reports and controlled investigations suggest that the addition of bupropion can be helpful for restoring sexual desire and may relieve delayed orgasm or anorgasmia in approximately 50% of patients.[5,79–82] This therapeutic effect has been demonstrated in depressed and nondepressed patients alike. A common dosing technique is to start with 150 mg of bupropion daily. If unsuccessful, the dose can be increased to 150 mg of bupropion sustained release (SR) twice daily after several days (or 300 mg of the extended-release [XL] preparation). The mechanisms of SSRI-induced sexual dysfunction, and bupropion relief, are not well understood, but likely due to the pro-sexual effects of increasing DA.[83]

Other remedies have been prescribed for SSRI-induced sexual dysfunction. A large randomized, controlled trial examined the impact of sildenafil on male patients suffering from this side effect.[84] Overall, 54% of patients randomly assigned to sildenafil found it to be effective compared with a 4% response rate with placebo. Open-label trials of sildenafil in women experiencing SSRI-induced anorgasmia have also reported improvements. Tadalafil has also shown similar efficacy suggesting a class effect.[85]

Amantadine, buspirone, and yohimbine also have been used successfully to reverse delayed ejaculation or decreased libido, but the evidence for efficacy is limited.[86–88] One small double-blind study compared the effects of amantadine with buspirone or placebo among depressed patients experiencing sexual dysfunction on antidepressants.[89] All three study treatments improved sexual dysfunction to a comparable extent, and the only statistically significant finding was related to an increase in energy reported among patients receiving amantadine (vs. placebo). An open-label trial of Ginkgo biloba in men and women with sexual dysfunction reported very high success rates, but mixed results have been reported in clinical practice.[90] Mirtazapine is capable of blocking postsynaptic 5-HT_2 receptors and has been shown to have less sexual dysfunction than SSRIs.[91] The 5-HT and histamine receptor antagonist cyproheptadine has been shown to alleviate this adverse event. However, due to its broad effect on all 5-HT receptors, depression relapse and serotonin withdrawal can occur resulting in it not being recommended. Finally, stimulants such as methylphenidate or dextroamphetamine may increase libido in SSRI-treated patients, but the potential for dependence and abuse discourages their routine administration.[92]

All antidepressants have a black box warning regarding the possibility of an increase in suicidal thinking, specifically in persons 24 years old and younger. In regard to completed suicide, the rate is less in adult and pediatric patients treated with antidepressants than those who are not treated.[5,26,93,94] However, studies have shown a rate in suicidal thinking among children and young adults of 4% in the medication arms compared to 2% in placebo arms.[94] Therefore, in order to protect the patient, it is recommended that when an antidepressant is initiated in a child or adolescent, the patient should visit with the clinician every week in the first month, every 2 weeks in the second month, and then monthly for the next month. Adults should also be monitored frequently, and weekly visits initially have shown increased adherence rates. However, other factors may play a role in monitoring such as access to care and distance the patient needs to travel for the appointment. Therefore, it is recommended to at least speak with the adult patient (e.g., via telephone) at least every 1 to 2 weeks in the acute phase (initial 12 weeks) of treatment to assess suicidality but also to check for side effects and adherence.[5,10] SSRIs are dramatically safer in overdose compared to tricyclic antidepressants and are preferred for those with suicidal thinking or comorbidities that put them at risk for impulsive acts of self-harm such as substance misuse.

In addition to GI, CNS, and sexual side effects, a variety of other, less-common adverse sequelae have occurred with SSRIs. Headache can occur with SSRIs at a rate of approximately 10% to 15% with all agents similar and slightly greater than placebo, with discontinuations due to headache very low at 1% to 3%.[95] This may be due to the effects of serotonin on 5-HT_{1b} and $_{1d}$ receptors. It is important to note that SSRIs are actually recommended for migraine prophylaxis as a second-line agent.[96,97] Increased sweating has also been reported with SSRIs and can be particularly uncomfortable or embarrassing.[98] A dosage reduction may help relieve this adverse effect and should be tried first. Adjunctive treatment of α-blockers (e.g., terazosin, prazosin), cyproheptadine, and the anticholinergic benztropine has shown some success if a dose reduction is not possible.[99,100] Bruxism, or teeth grinding, can also be a consequence of SSRI treatment, leading to chipped or cracked teeth and generally poor dentition.[101] Often, patients may not be aware of this nocturnal effect and complain merely of a dull, persistent headache during the morning hours. This, too, may be a dose-dependent side effect of all SSRIs, and several antidotes have been prescribed (e.g., buspirone, benzodiazepines, gabapentin).[102,103] In small retrospective studies and several case reports, SSRIs have been linked to dilutional hyponatremia or syndrome of inappropriate antidiuretic hormone (SIADH).[104,105] All SSRIs and SNRIs have been associated with this phenomenon, and elderly patients appear to be uniquely at risk.

SSRIs have been rarely associated with extrapyramidal side (EPS) effects, consisting of akathisia, dystonias, and parkinsonian symptoms that are qualitatively identical to those seen with antipsychotics.[106–108] Although EPS reactions have been documented with all SSRIs, most case reports have correlated with aggressive dosing, often in a patient currently using a DA antagonistic medication, and during the first 1 to 4 weeks of initiation. The theory is that these EPS effects are mediated through the indirect influence of serotonergic neurons on dopaminergic activity.[107] In certain areas of the brain, serotonin and dopamine appear to have an inverse relationship, whereby central stimulation of serotonin receptors results in a net decline in dopaminergic transmission. Management of EPS effects induced by SSRI is identical to that of those precipitated by antipsychotics. Dystonias and parkinsonian side effects can be treated with anticholinergic agents and subsequent SSRI dosage reduction. Akathisia usually responds to a reduction in SSRI dosage and/or administration of low-dose β-blockers.[108]

The long-term effects of SSRIs on body weight are variable and difficult to predict. A problem with accurate measurement is because decreased appetite is one of the most common depressive symptoms and that a small weight gain after an antidepressant course may actually be viewed as a therapeutic effect of successful treatment. Conversely, early reports of weight loss with fluoxetine generated much optimism for the use of SSRIs in obesity, but longitudinal studies found this to be a brief, transient phenomenon.[109] All the SSRIs have been reported to cause significant weight gain in long-term use, but it is a rare phenomenon believed to be mediated by genetic markers that have not been conclusively identified. The exception is paroxetine, which has been implicated much more often than other SSRIs as a cause of weight gain. One long-term RCT compared the effects of fluoxetine, sertraline, and paroxetine on total body weight.[110] After 7 months of SSRI use, 25% of the patients receiving paroxetine gained a clinically significant amount of weight (defined as a >7% increase in total body weight) compared with 7% with fluoxetine and 4% with sertraline.[110] Long-term studies with citalopram and escitalopram suggest that 3% to 5% of patients will experience a significant weight gain. The risk of SSRI weight gain is minimal (except with paroxetine) and typically irrelevant, but because appetite changes are part of depression, it is best to monitor weight closely during long-term treatment for both disease- and drug-related reasons.

Epidemiologic studies have also linked SSRIs and SNRIs with an increased risk for upper GI hemorrhage, with a number needed to harm of 3,177.[111,112] Recent trials suggest that the risk is modest but can be increased significantly by concurrent ingestion of NSAIDs lowering the number needed to harm of 881.[112–114] Alcohol use can also increase the risk of bleeding.[113,114] The mechanism for SSRI-induced GI hemorrhage has been attributed to effects on decreasing platelet activation and aggregation. SSRIs and SNRIs should be avoided in patients with active GI bleeds, and the concurrent use of high-dose NSAID should be discouraged.

DOSAGE TITRATION

CASE 86-1, QUESTION 3: AR and the clinician agree to start escitalopram 10 mg QAM. What is considered the standard of care and expected outcomes for dosing and efficacy?

It is very important to establish realistic expectations for treatment with antidepressants from the beginning of therapy. Patients should be informed of the anticipated course of treatment and that the onset of side effects usually precedes that of therapeutic effects. Also, patients should be advised that, although antidepressants may relieve acute depressive symptoms and prevent relapse, they do not abolish environmental stressors such as an abusive relationship or an oppressive work setting.

After receiving the medication for 2 weeks, most improvement in A.R. is likely due to the support she is getting by being involved in treatment as placebo patients show a reduction in symptoms during this period. Medication will start to separate from placebo typically at the 2-week monitoring period and continue to enlarge that separation from placebo up until week 8. A.R. should be reminded that the optimal effects of antidepressants may not be evident for another 4 to 6 weeks. Therefore, a reasonable recommendation would be to continue with the current daily dose of 10 mg and to re-evaluate the medication's effects when she returns to clinic in 2 weeks. If there is no clear improvement at 4 weeks, then switching the medication is necessary. If there is a 25% or more improvement, then the clinician could continue for another 4 weeks (for 8 weeks of treatment) and decide whether the response is acceptable. If the improvement is small, such as just 25% to 30%, then one can increase the dose at this 4-week point and continue to monitor for another 8 weeks.[5,10,26]

DURATION OF TREATMENT

According to the guidelines issued by the Agency for Health Research and Quality, antidepressant treatment can be broken down into three stages (Table 86-10).[115] The first stage, acute treatment, lasts approximately 12 weeks; during this time, the clinician attempts to resolve the presenting symptoms and induce remission which is defined as no impairing symptoms of depression and a score of ≤7 on the $HAMD_{17}$ or ≤10 on the MADRS.[5,10] The second stage is commonly called continuation treatment because the patient continues to receive the same antidepressant regimen that induced the initial treatment response, and the clinician attempts to keep the acute symptoms in remission. The duration of continuation treatment is variable (4–9 months after initial treatment or response), but it is recommended that all patients suffering from major depression complete these first two stages. Therefore, the minimum duration of treatment is 7 months. Alternatively, others have advocated that the minimum duration of treatment should be for 6 months after the complete resolution of symptoms.[5]

Table 86-10

Duration of Antidepressant Treatment

Acute treatment phase	3 months
Continuation treatment phase	4–9 months
Maintenance treatment phase	Variable

- Acute and continuation treatment recommended for all patients with major depressive disorder (MDD) (i.e., minimal duration of treatment = 7 months)
- Decision to prescribe maintenance treatment is based on the following:
  - Number of previous episodes
  - Severity of previous episodes
  - Family history of depression
  - Patient age (worse prognosis if elderly)
  - Response to antidepressant
  - Persistence of environmental stressors
- Indefinite maintenance treatment is recommended if any one of the following criteria is met:
  - Three or more previous episodes (regardless of age)
  - Two or more previous episodes and age older than 50 years
  - One or more and age older than 60 years

The third stage of treatment, maintenance treatment or prophylaxis, is not indicated for all patients, and the necessity of continuing medication beyond the first 6 to 7 months depends on many patient-specific factors. One must consider the number of previous episodes, family history of depression, patient's age, severity of presenting symptoms, response to therapy, and persistence or anticipation of environmental stressors. There are specific populations for whom indefinite pharmacologic treatment is advocated: (a) individuals with three or more previous episodes of major depression, (b) individuals older than 50 years with two or more previous episodes, and (c) individuals older than 60 years with one or more previous episodes.[5,10] Continued antidepressant usage in the elderly is recommended to prevent relapse.[116]

Because A.R. is exhibiting a full therapeutic response to escitalopram, the recommendation would be for her to continue with the effective dosage (10 mg/day) for at least 7 consecutive months. At the end of this time frame, the clinician should review with the patient those considerations that enter into the decision to continue treatment. Ultimately, the decision to continue antidepressant medications is left to the patient's judgment, and he/she should be well informed of the potential consequences of stopping treatment.

In the future, if A.R. decides to discontinue her antidepressant she should fully disclose this to her prescriber so that an appropriate taper schedule and subsequent monitoring can occur. She should be advised of potential withdrawal symptoms (Table 86-11).[117] Abrupt discontinuation of chronic SSRI treatment (e.g., treatment >2 months) has been associated with dizziness, headache, anxiety, lethargy, dysphoria, and sleep problems.[5,117] The onset of these symptoms is generally within 36 to 72 hours of stopping treatment, and effects may persist for approximately a week. Withdrawal symptoms generally are mild and self-limiting but can be uncomfortable and alarming. Because of their relatively short half-life (and absence of long-acting metabolites), paroxetine, fluvoxamine, and venlafaxine have been associated with a more profound withdrawal presentation than other SSRIs and SNRIs. Due to its long half-life (and that of its active metabolite), fluoxetine has not been commonly associated with withdrawal symptoms. Nonetheless, it is advisable to taper slowly off all antidepressant medications after an extended treatment course to decrease the risk of withdrawal and subsequent relapse.[118] A defined time for taper has not been established. Switching therapies within classes can be done quickly (e.g., from sertraline to fluoxetine) without a cross-taper. When switching to another class or off antidepressant completely then a 6 to 8 week taper is standard as well as educating the patient to withdrawal symptoms and reassuring them that this is not a life-threatening event. Because withdrawal is not life-threatening, a much faster taper (3–7 days) can be completed with the patient's approval.[10,117]

Table 86-11

Discontinuation of Antidepressants

Withdrawal syndrome

- Worse with paroxetine, venlafaxine
- Symptoms: dizziness, nausea, paresthesias, anxiety/insomnia, flulike symptoms

- Onset: 36–72 hours
- Duration: 3–7 days

Note: Risk of depression relapse is greatest 1 to 6 months after discontinuation.

Suicide Assessment

Patients with major depression should always be assessed for the presence of suicidal thoughts (e.g., “Do you ever feel like giving up?” “Are you thinking about hurting yourself?”). Reports have noted that completed suicide rates range from 2% to 15%. Up to 70% of suicides worldwide are persons with MDD.[5,119] Comments made by the patients alluding to suicide (e.g., “Life is not worth living anymore,” “I am leaving and may never see you again”) should be taken seriously. Several factors may place a person at greater risk for a suicide attempt. These include living alone, having a disabling illness, being unemployed, having a history of alcohol/drug abuse, chronic pain, anxiety, or having a family history of suicide.[10] Gender plays a role as well, with women much more likely to attempt suicide, although men are more likely to complete the act.[10]

For patients who are actively suicidal, hospitalization is often necessary and may be facilitated against the patients will in high-risk settings. Other life-saving interventions include establishing close contact with the patient’s family and healthcare provider, convincing the patient to contract for his/her safety and ensuring that firearms and other lethal means are removed from the home. Antidepressants have different risks of lethality in overdose. Tricyclics are by far much more dangerous than SSRIs. Duloxetine, venlafaxine, and mirtazapine are a much lower risk than TCAs but higher than SSRIs. Among the SSRIs, citalopram has the greatest risk of cardiotoxicity in overdose but still less than venlafaxine.[5] For patients who are at risk for attempting suicide, TCAs and MAOIs are contraindicated.

A.R. is at some risk for suicide, although she does not have a detailed plan at present. She should be monitored closely during the first few weeks of therapy by friends or family members. If her suicidal ideation becomes severe, A.R. should be evaluated at a psychiatric emergency room for her own safety. Unfortunately, it is not always possible to predict whether A.R. (or any depressed patient) will attempt suicide. Even with the most conservative precautions, a small percentage of patients successfully complete their suicide attempts.

CASE 86-1, QUESTION 4: After A.R. has been treated for a year she is asking about coming off her escitalopram partly because she is getting married and considering becoming pregnant. What would be the most appropriate way to proceed with discontinuation and treatment of depression during pregnancy?

A.R.’s escitalopram should be tapered during several weeks (e.g., decrease to 5 mg daily for 2–4 weeks, then discontinue). The risk of relapse is relatively low during the first month off medication, but depressive symptoms often return during the second or third months. The risk of relapse is highest during the first 6 months after therapy is stopped.[120]

Antidepressants in Pregnancy and Lactation

The risk for depression is elevated during pregnancy and during the postpartum period.[121] A prospective investigation reported that women who discontinued their antidepressant on learning, when they were pregnant, were much more likely to relapse prior to delivery (68% relapse rate vs. 26% who continued treatment; hazard ratio, 5.0).[122]

Before deciding to treat with an antidepressant during pregnancy, one should make a careful inventory of the benefits and risks. The consequences of maternal depression on the mother and fetus must be compared with the potential risks of in utero medication exposure. From the mother's perspective, untreated depression carries with it a great deal of distress during an emotional time. Sleep and appetite may be compromised at a time when these functions are most important for the baby's development. Mothers may also be tempted to drink alcohol or abuse substances, and studies have also shown that depressed mothers are much less likely to attend prenatal clinic visits.[123] Depression during pregnancy is a very strong risk factor for postpartum depression.

Most of the SSRIs and newer antidepressants pose little risk for the development of serious fetal malformations, and they have been subsequently categorized as Class C by the FDA (suggesting that the risk to the fetus is not definitively known). Their relative safety has been corroborated by two large case–control studies in which very small increases in risks were reported.[124,125]

One notable exception is with paroxetine, which was reclassified as Class D by the FDA after the demonstration of an increased risk for congenital heart defects in newborns.[126] An additional concern with SSRIs and SNRIs in pregnancy is the risk for a neonatal serotonin withdrawal syndrome immediately after delivery. This has been reported with TCAs in the past as well. A small controlled investigation (n = 40) examined the effects of fluoxetine and citalopram on CNS effects in newborns and found a significant increase in restlessness, tremor, shivering, and hyper-reflexia during the first 4 days of life (vs. controls); these signs spontaneously remitted shortly thereafter.[127] Although some clinicians have interpreted these findings to suggest that antidepressants should be tapered and discontinued prior to delivery, others have argued that the delivery and the postpartum periods are major stressors for the new mother, and the risk of relapse during this time would be unacceptably high if the medication is withdrawn. Studies have also reported a small but significant decrease in birthweight among babies exposed in utero to SSRI although a prospective study found that neither depression or SSRI use effected infant growth.[128] Clinicians should be reminded, however, that both of these findings have been consistently reported with depression in the absence of antidepressant treatment, and attempts to distinguish the effects of the illness from medication effects in pregnant women have met with mixed results.[129] The safety of bupropion in pregnancy has not been extensively studied.

A recent review of animal studies uncovered an increased risk of congenital abnormalities, but retrospective reviews in humans have failed to identify an enhanced risk of fetal malformation or spontaneous abortions. Due to these findings in animal trials, the FDA recently changed bupropion to a Class C rating. Data are even more sparse with mirtazapine, venlafaxine, or duloxetine, but no obvious adverse effects have been identified among infants exposed to these antidepressants in utero. Similarly, fetal malformations have been rarely reported with TCAs and they are generally regarded as safe in pregnant women. MAOIs, however, should be avoided due to increased risks for hypertensive crises. Although screening for depression is not suggested in the general population, it is recommended specifically for those who are pregnant and postnatal.[130] If antidepressants need to be used, then monotherapy is best; avoid first-trimester exposure, do not stop the antidepressant abruptly, and do not discontinue prior to delivery due to the high risk of postpartum depression.[123]

For A.R., it is important to assess her risk for depression if she stops taking her antidepressant. This was her first episode of depression (which occurred under stressful circumstances), she is not currently symptomatic, and she does not have a strong genetic predisposition to mood disorders. If she is committed to starting a family, she should consider tapering off her escitalopram for several weeks before attempting to conceive. If she becomes pregnant and her depression returns, the risk to the fetus appears to be quite low with most SSRIs. Theoretically, this risk can be reduced further if the antidepressant is started after the first trimester (when most major fetal development occurs). An additional option for pregnant mothers suffering from mild-to-moderate symptoms would be to consider psychotherapy.[123,131]

Approximately 70% of new mothers report sadness or anxiety during the first few days after delivery (baby blues), but these feelings will usually resolve within 1 to 2 weeks and do not require treatment. Approximately 10% of mothers will experience unremitting symptoms postpartum that ultimately satisfy criteria for MDD. The onset of these symptoms can be quite variable, ranging from the immediate postpartum period to several months later. Although psychotherapy may be appealing and obviate the need for medication exposure via breast milk, it is often inconvenient and impractical for new mothers to leave the house on a weekly basis without their infants. Antidepressant medications, therefore, are frequently prescribed to manage postpartum mood disorders. Not treating depression postpartum results in symptom-related risks to the mother and newborn. Therefore, the priority is on reducing depression, and if an antidepressant is the most effective option for the mother then efforts should be placed on managing breast-feeding.[132]

Because breast-feeding is widely advocated, the passive transfer of medication from mother to infant must be considered. Studies with TCAs and SSRIs suggest that concentrations of some antidepressants in breast milk are measurable. However, subsequent concentrations in the infant's bloodstream are relatively low, and the sequelae from this exposure have been limited to scattered case reports of increased infant irritability. Among the available agents, fluoxetine and the tricyclic antidepressant doxepin have been associated with the highest concentrations in infants, and although the clinical or developmental consequences of this finding have not been elucidated, it has been recommended that these medications be avoided.[133] Recent studies with SSRIs suggest that the concentrations achieved in breast milk are lowest with sertraline, and that paroxetine, citalopram, escitalopram, bupropion, and venlafaxine are somewhere between the extremes of fluoxetine and sertraline.[132–134] If an antidepressant is to be continued in a mother who is breast-feeding, the lowest dosage should be prescribed. Concentrations of SSRIs in breast milk will generally peak approximately 4 to 8 hours after oral administration. If a new mother is particularly concerned about breast milk exposure, she can be advised to pump and save breast milk immediately prior to taking the antidepressant.

Drug Interactions

The SSRIs are inhibitors of the cytochrome P-450 isoenzymes, but important differences exist among the individual agents in their potency for specific metabolic pathways (Table 86-8). For instance, the cytochrome P-450 1A2 isoenzyme (or CYP1A2) is most sensitive to the inhibitory effects of fluvoxamine. Fluoxetine and paroxetine have the highest impact on CYP450 2D6 with fluoxetine resulting in approximately fourfold increase in TCAs and paroxetine a fivefold increase.[70,135] Fluoxetine's active metabolite has weak-to-moderate inhibitory effects on the CYP3A4 isoenzyme. In comparison, sertraline, citalopram, and escitalopram have a much lower potential for CYP450 2D6 drug interactions but still inhibit the metabolism of 2D6-dependent medications. The potency is typically between 30% and 50% increases in AUC and is often clinically irrelevant. Therefore, CYP450 2D6 drug interactions are less likely to cause harm with sertraline, escitalopram, citalopram, and fluvoxamine, but still require monitoring for a few weeks after the antidepressant is added to the patients' medication list.[70,135–138]

Although in vitro affinities of antidepressants for the respective isoenzymes can be very helpful for predicting potentially dangerous drug combinations, there is wide interpatient variability in the intensity of these interactions. Much of this variability can be attributed to genetic polymorphism. With CYP2D6, for example, approximately 5% to 10% of Caucasian patients and 1% to 2% of Asian patients are considered poor metabolizers via this isoenzyme.[139] CYP3A4 is the most abundant CYP enzyme found in the human body. Among the SSRIs, only fluoxetine and fluvoxamine have weak and moderate inhibitory effects on this isoenzyme, respectively. This has resulted in approximately 50% to 150% increase in AUC of the CYP450 3A4-dependent drug alprazolam.[70,137]

SEROTONIN SYNDROME

Serotonin syndrome is a rare but potentially fatal interaction due to excessive and prolonged serotonin within the synapse.[140] The syndrome includes a constellation of symptoms, including anxiety, shivering, diaphoresis, tremor, hyper-reflexia, and autonomic instability (increased/decreased blood pressure and pulse rate).[140] Fatalities have been attributed to malignant hyperthermia. It occurs due to excessive serotonin overstimulating 5-HT$_{1a}$ receptors and possibly 5-HT$_{2a}$ (hyperthermia, incoordination, and neuromuscular effects).[140] It can occur within hours of administration of medications that can cause the syndrome. With mild cases of serotonin syndrome, the symptoms ordinarily resolve 24 to 48 hours after the serotonergic agents have been discontinued. Supportive treatment may be necessary, and for more severe reactions, the serotonergic antagonist cyproheptadine is most commonly prescribed.[140] Dantrolene has been administered successfully to manage hyperthermia.[141]

Excessive serotonin can occur via four mechanisms: preventing its breakdown, preventing its reuptake into the neuron, increasing precursors or agonists, and increasing its release. Most case reports of serotonin syndrome (and most fatalities) have occurred with a combination of an MAOI and an SSRI, which is considered a contraindication. Other case reports involve the combination of an MAOI (or SSRI) with tryptophan, meperidine, SNRI, tricyclics, dextromethorphan, linezolid, and tramadol.[140] One case of serotonin syndrome was reportedly induced by the combination of clomipramine with S-adenosylmethionine (SAM-E).[142] Theoretically, the combination of an SSRI with Saint-John's-wort may also

---

precipitate this pharmacodynamic interaction, but more recent evidence has suggested that the MAOI properties of the herbal preparation are minimal with therapeutic doses. Nonetheless, a case series of five older patients who exhibited symptoms reminiscent of serotonin syndrome has appeared in the literature, and, given the degree of uncertainty that persists, this combination of antidepressant agents is best avoided.[143] As noted by the previously described reports, the most concerning risk is combining agents that increase serotonin via differing mechanisms such as inhibiting the enzyme monoamine oxygenase and blocking the serotonin reuptake pump. Serotonin syndrome has also been reported with concurrent administration of multiple SSRIs; however, this would generally not be fatal. It is important to note that many medications have MAO inhibitory effects although they are not classified as an

MAOI. This would include medications such as linezolid, dextromethorphan, and meperidine.

The combination of trazodone with an SSRI could possibly pose some concern because both classes of antidepressants augment serotonin activity in the CNS yet; because both are reuptake inhibitors, it is very unlikely. Trazodone has been associated with serotonin syndrome in two incidences, one involving the coadministration of buspirone and the other associated with a concomitant MAOI.[144] However, in practice, trazodone is recommended and is commonly prescribed to patients receiving an SSRI for the treatment of insomnia, with no confirmed cases of serotonin syndrome that have surfaced in the medical literature thus making it a possible risk only at very high doses.[145,146]

CASE 86-2

QUESTION 1: M.G. is a 35 year old married female. She is diagnosed with MDD and has been tried on sertraline up to 100 mg QAM for 8 weeks which did not result in a response. She was then tried on fluoxetine 20 mg QAM for 8 weeks with only a partial response. What is the next step for M.G. who has not responded to two antidepressant trials at a therapeutic dose for a therapeutic duration?

Pooled results of clinical trials suggest that the majority of patients with major depression receiving an adequate trial of any antidepressant will have a therapeutic response, defined as at least a 50% reduction in depressive symptoms. However, for a patient who is severely depressed, a 50% reduction in symptoms still leaves him/her with significant psychopathology and associated disability. Consequently, full remission is the preferred therapeutic end point.[5] The STAR*D trials showed that after four stages of treatment (medication or psychotherapy), 33% of patients fail to reach remission.[147] In addition, with each course of antidepressants, people were less likely to achieve remission. One longitudinal investigation found that patients with residual symptoms were 3 times more likely to suffer relapse during the 12 months after treatment than those who had remitted.[148] Not surprisingly, patients with treatment-resistant depression have 40% higher direct medical costs than those without treatment-resistant depression, mainly due to medication and outpatient care costs.[149]

For M.G., the first step would be to confirm her diagnosis and rule out potential medical explanations for her symptoms, specifically bipolar disorder. Bipolar depression is diagnostically indistinguishable from MDD depressed episodes. Because antidepressants are minimally effective in bipolar depression, it would explain MGs lack of response if she were to have bipolar disorder. Iatrogenic causes should also be explored, such as any new medications or substance misuse. Assessing adherence to her previous medication trials is critical. A full therapeutic trial is considered to be a minimum of 4 weeks of treatment at a dosage shown to be clinically effective assuming the patient is compliant with therapy.

Drug Selection

SEROTONIN NOREPINEPHRINE REUPTAKE INHIBITORS

Because 30% to 40% of patients will effectively achieve remission and about 20% to 25% of patients will stop an antidepressant because of side effects, many patients started on a given antidepressant may eventually need a significant adjustment or change to their original regimen.[10]

In M.G.'s case, she has previously failed a therapeutic trial of sertraline and fluoxetine. Although she had failed a sertraline trial, large controlled investigations suggest that 50% to 70% of patients who are unresponsive or intolerant of one SSRI will experience a therapeutic response to a different SSRI.[150–152] For example, in the STAR*D trial, patients failing an initial course of citalopram were just as likely to respond whether they were randomly assigned to a subsequent trial of a different SSRI (sertraline) because they were to other antidepressant classes (venlafaxine and bupropion, specifically).[153] Because M.G. has now failed two SSRIs, it is recommended to try an antidepressant from a different class such as an SNRI, α 2 antagonist, or DA reuptake inhibitor.[5,10] For M.G., it was recommended to use an SNRI and duloxetine was selected.

SNRIS

Venlafaxine, duloxetine, desvenlafaxine, and levomilnacipran are categorized as serotonin/norepinephrine reuptake inhibitors (SNRIs) (Table 86-7). At dosages less than 150 mg/day, venlafaxine's therapeutic effects are mediated exclusively from the blockade of serotonin reuptake. Therefore, associated adverse effects at these dosages are qualitatively and quantitatively very similar to those found with SSRIs: GI distress, sleep disturbances, and sexual dysfunction. At higher dosages, effects on NE occur, and this can lead to the emergence of different adverse effects (e.g., tachycardia and hypertension) and insomnia. NE effects occurring with duloxetine, desvenlafaxine, and levomilnacipran do not appear to be dose-dependent.[154] Levomilnacipran is an SNRI that has more potent effects on NE as compared to its 5-HT reuptake. However, its potency at NE reuptake is similar to duloxetine, and the ratio difference is due to its lower potency at 5-HT reuptake than the other SNRIs.[155,156] Venlafaxine, which is available as immediate- and extended-release formulations, has a relatively brief plasma half-life (5–8 hours) and is demethylated to an active metabolite (O-desmethyl-venlafaxine). This metabolite, desvenlafaxine, was approved by the FDA in 2008 for the treatment of depression. Desvenlafaxine is available as an extended-release tablet that has a similar mechanism of action as venlafaxine. It has no affinity for muscarinic, histaminic, cholinergic, or adrenergic receptors and has a terminal half-life of 11 hours.[157,158] Desvenlafaxine is not affected by CYP2D6 inhibitors; however, CYP3A4 inhibitors may reduce clearance of the drug.[138] Duloxetine also has a relatively short half-life (12 hours) and is metabolized via CYP450 1A1. Levomilnacipran is mainly metabolized by CYP3A4 with a terminal half-life of 12 hours and is available as an extended-release tablet.[159] Venlafaxine, desvenlafaxine, and levomilnacipran are not potent inhibitors of cytochrome P-450 isoenzymes. Duloxetine is a moderate inhibitor of the CYP2D6 isoenzyme.[138,159] As with SSRIs, SNRIs have been associated with serotonin syndrome. Additionally, increased BP will occur if combined with an MAOI.

As a class, all SNRIs have a risk of increasing blood pressure and heart rate thought to be due to the increase in NE. Venlafaxine averages an increase of 1 mm Hg and 3 bpm.[160] Duloxetine averages 1 mm Hg in BP and 3 bpm.[161] Desvenlafaxine averages an increase of 2 mm Hg and 4 bpm.[162,163] Levomilnacipran has the greatest risk and averages an increase of 4 mm Hg in BP and 8 bpm compared to placebo.[164] There will be some patients who

---

have large changes in BP with any of the SNRIs; thus, monitoring of vital signs is necessary a few weeks after every dose increase.

Duloxetine has also been shown to increase LFTs 3 times the upper limit of normal by approximately 1.3% compared to 0.2% in placebo-treated patients.[165] Although these numbers are small and similar to other antidepressants, the FDA has given duloxetine a warning that it is not to be prescribed to patients with substantial alcohol use or evidence of chronic liver disease.[165] Levomilnacipran has also been shown to mildly increase LFTs at initiation of therapy.[159]

CASE 86-2, QUESTION 2: M.G. is given a prescription of duloxetine 30 mg QAM yet she has heard from television ads about a new antidepressant called Trintellix (vortioxetine) that is different than SSRIs. She asks if you can explain how this new antidepressant is different and if it is really better than the duloxetine she has just been prescribed.

SSRI and Serotonin Receptor Modulators

Vilazodone and vortioxetine are members of a new class of antidepressant. These medications have their primary effect on depression via inhibition of the serotonin reuptake pump, like the SSRIs (Table 86-10). These two agents also have potency at other serotonin receptors. Vilazodone is a partial agonist at the 5-HT$_{1a}$ receptor.[166] Vortioxetine is a 5-HT$_{1a}$ agonist, 5-HT$_{1d}$, 5-HT$_{3}$, 5-HT$_{7}$ antagonist, and 5-HT$_{1b}$ partial agonist. Despite the potential for the added serotonin receptor effects, head-to-head trials with SSRIs and SNRIs have shown no greater efficacy advantage and similar side effect profiles.[164,166–168] In two separate studies, vortioxetine 20 mg showed a slightly less reduction in MADRS compared to duloxetine 60 mg QAM, –15.57 versus –16.9, respectively and –18.8 versus 21.2, respectively.[169,170]

Vilazodone should be taken with food as this increases absorption by about 50%.

It is metabolized primarily by CYP450 3A4 and secondarily through 2C19. Inhibitors and inducers have a small effect on blood levels. Its half-life is approximately 25 hours.[171] Vilazodone seems to have no effect on CYP450 isoenzymes.[138] Vortioxetine is metabolized via multiple CYP 450 pathways with 2D6 being the primary one. It has a half-life of approximately 60 hours. It does not appear to effect the metabolism of other drugs using CYP450 (Tables 86-7 and 86-8).[172]

When speaking with M.G., it would be accurate to state that the new medication is not likely to be any better than her current prescription. Monitoring vital signs is more important with duloxetine than with vortioxetine although the change in vital signs with duloxetine is minimal and usually clinically irrelevant. Duloxetine has a potential for inhibiting CYP450 2D6 that is greater than vortioxetine. Duloxetine should be titrated to 60 mg QAM; thus, a dose increase is necessary to monitor for a therapeutic response (Table 86-9).

OTHER AGENTS: BUPROPION, MIRTAZAPINE, TRAZODONE, AND NEFAZODONE

Bupropion is an aminoketone with a mechanism of action that is clearly different from that of any other antidepressant because its therapeutic effect is due primarily to DA reuptake inhibition and has negligible effects on serotonin (Table 86-7).[173] This lack of serotonin provides a benefit in regard to both a lack of sexual dysfunction and sedation but has the negative effect in that it is definitively less anxiolytic as compared to the proserotonergic effect of the other antidepressants.[5] At therapeutic dosages, bupropion has a different adverse effect profile compared to SSRIs and SNRIs. Nausea, insomnia, agitation, and jitteriness are the most common, likely due to the stimulatory effect of DA. Seizures are a risk but are unlikely with therapeutic dosing of bupropion, provided that patients are not predisposed (e.g., history of epilepsy, bulimia, electrolyte abnormalities, or recent history of heavy drinking). Bupropion may decrease appetite. A randomized, placebo-controlled investigation of bupropion in depressed obese patients observing caloric restriction found that bupropion was much more likely to induce significant weight loss than placebo.[174] After 26 weeks of treatment, 40% of the bupropion-treated patients lost more than 5% of their total body weight versus 16% with placebo. This weight loss was positively correlated with an improvement in depressive symptoms. It has little-to-no negative effect on sexual function due to no stimulation of 5-HT receptors. For patients who develop sexual dysfunction from the SSRI or SNRI, bupropion has shown some benefit as an adjunctive treatment that reduces the side effect. It is also useful for poor responders as an adjunct to SSRI/SNRI due to its unique neurotransmitter effect.[5] Bupropion does not seem to affect cardiac rhythm or induce arrhythmias in susceptible patients.[175] Patients with hypertension should be monitored for increases in BP if bupropion is initiated.[176]

Bupropion is converted via the cytochrome CYP450 2B6 isoenzyme to an active metabolite (9 hydroxybupropion). Bupropion (and its metabolite) appears to have a moderate effect at inhibiting the CYP450 2D6 isoenzyme, and significant elevations of venlafaxine and metoprolol have been demonstrated to occur with concurrent administration (Table 86-8). Because of its short half-life (approximately 8 hours for the parent compound and 12 hours for the active metabolite), therapeutic doses of regular release bupropion must be administered in divided doses. The recommended starting dose is 100 mg twice a day (BID), increasing to 100 mg 3 times a day (TID) after at least 3 days. Individual doses must not exceed 150 mg and should be given at least 6 hours apart. For the SR formulation, initial daily doses are 150 mg every day, increased to 150 mg BID by the fourth day at the earliest. Individual doses of bupropion SR can be as large as 200 mg, and divided doses should be given at least 8 hours apart. The once-daily formulation is initiated at 150 mg daily and increasing to 300 mg daily as early as the fourth day. Maximum daily doses are 450 mg for regular and XL products, and 400 mg for SR products (Table 86-9). Maximum doses should be strictly followed due to the dose-dependent risk of seizures.[10]

Mirtazapine is a novel antidepressant capable of modulating serotonin and NE activity through a complex mechanism of action. In vitro studies reveal that mirtazapine is an antagonist at presynaptic α_2-autoreceptors and postsynaptic 5-HT_2 and 5-HT_3 receptors.[177] In addition, it appears to possess some mild inhibitory properties at serotonin reuptake transporters. Therefore, the net effect of mirtazapine is to enhance serotonin and NE in a manner that is clearly distinct from any other antidepressants (Table 86-8). In a comparative randomized trial with fluoxetine for moderate-to-severe depression, mirtazapine appeared to be much more effective than fluoxetine after 4 weeks of treatment (58% responders vs. 30% with fluoxetine; $P<0.05$), but the differences were no longer significant at 6 weeks (63% vs. 54%; $P = 0.67$).[178]

The most common adverse effects experienced with mirtazapine are sedation and weight gain. Because mirtazapine has potent antihistaminergic effects, it can be quite sedating and is often used as a hypnotic similar to trazodone. Unlike trazodone, antidepressant dosing is quite tolerable. Anecdotally, it has been reported that higher daily doses of mirtazapine (>30 mg) are less sedating than lower doses owing to a plateauing of antihistaminic effects at 15 mg but an increase in noradrenergic effects up to 60 mg. In addition to the substantial risk of increasing appetite and total body weight, mirtazapine has been associated with significant increases in total cholesterol and triglycerides. This is likely due to its combination of H_1 and 5-HT_{2c} antagonism, the pharmacology related to atypical antipsychotic metabolic effects.

This makes mirtazapine less preferred than SSRIs in the diabetic patient. Mirtazapine does not appear to affect cardiac rhythm or induce arrhythmias.[175] The recommended starting dosage is 15 mg at bedtime, and the therapeutic dosage ranges from 15 to 45 mg/day (Table 86-9).[179] Data from controlled trials have demonstrated safety and efficacy in doses up to 60 mg daily.[179–181] As with bupropion, mirtazapine is considered a top choice for antidepressant combination therapy in poorly responding patients on an SSRI/SNRI. Despite the fact that mirtazapine is increasing 5-HT and NE as do SNRIs, its unique method of doing this via α2 antagonism makes the combination with an SNRI or SSRI recommended.[5,10,182]

Nefazodone and trazodone have similar mechanisms of action. Both are serotonin reuptake inhibitors but nefazodone also has a mild NE reuptake inhibitory effect (Table 86-7). Both also block 5-HT_2 receptors.[17] This particular characteristic has resulted in very little sexual dysfunction, and switching studies have shown that patients who develop sexual side effects with SSRIs do not have this side effect with nefazodone.[183] Interestingly, trazodone does have the rare but well-documented side effect of priapism.[184] Trazodone, which comes as immediate-release and an extended-release caplet, is rarely used for depression due to its potency of H_1 antagonism centrally resulting in significant sedation and somnolence.[10,146,184] Antidepressive effects with trazodone occur above 150 mg a day with most patients requiring >300 mg a day, yet sedation occurs at low doses such as 25 mg.[184,185] This has caused clinicians to use trazodone as a hypnotic with other antidepressants instead of trying to titrate up and use it as monotherapy. It is also a potent α 1 receptor antagonist and can cause orthostasis.[10,184] A reason that nefazodone has not been used more is due to its potential for hepatotoxicity.[5,10] This event is more common than any other antidepressant. With appropriate monitoring, such as LFTs q3 months for the first 18 to 24 months, this risk is nearly eliminated.[10] However, other drugs with hepatotoxic risks such as valproic acid increase this risk making nefazodone more difficult to use than most other antidepressants. Nefazodone is metabolized via CYP450 3A4 and is also a moderate-to-strong inhibitor of CYP450 3A4 (Table 86-8).[76,186]

TCAs

The SSRIs are recommended over TCAs in the treatment of mood disorders. The popularity of SSRIs can be attributed to numerous advantages over older compounds, including a lower side effect burden, safety in overdose, less dosage titration, and patient preference.[5,10,26] Results of a meta-analysis concluded that although the overall efficacy of the SSRI and TCA classes was comparable, primary care patients receiving an SSRI were much less likely to discontinue therapy prematurely due to side effects.[187] TCAs cause a variety of adverse effects, ranging from bothersome (dry mouth, sedation, constipation) to serious (cardiovascular effects), which often prevent patients from receiving therapeutic doses of medication.[188] Patient adherence with prescribed medication may also be compromised with TCAs.[189] Even though SSRIs and the newer SNRIs are preferred for treatment of depression, TCAs continue to be prescribed at low doses for other indications that are comorbid with depression (e.g., migraine prophylaxis, chronic neuropathic pain). This requires careful monitoring for drug interactions as TCAs as a class are primarily metabolized via CYP450 2D6 and, as noted previously, some SSRIs and SNRIs may inhibit this pathway substantially increasing the risk of TCA toxicity.

SIDE EFFECTS

Therapeutic effects of TCAs are primarily through their ability to inhibit the reuptake of serotonin and NE, functionally an SNRI (Table 86-7).[190] Additionally, TCAs have significant effects on acetylcholine, histamine, and α noradrenergic receptors all of which are considered potential for side effects. The intensity of these side effects has been shown to adversely affect adherence.[26] Although patients may develop tolerance to these effects, they may never disappear completely.

Due to the potent histamine 1 antagonism centrally, TCAs can be very sedating and are usually administered at bedtime to minimize functional impairments. Confusion or memory deficits may also occur with TCAs and can be particularly onerous in elderly patients. The secondary amines may be more tolerable in this regard, but all TCAs can impair concentration or alertness to some extent and are not recommended in geriatrics.[10] The sedating antihistaminic effect (along with orthostasis) increases the risk of falls. The risk of weight gain and constipation make TCAs undesirable in a patient with comorbid diabetes.

Orthostatic hypotension is the most common and troublesome cardiovascular effect of the TCAs (as well as MAOIs) because it can result in significant morbidity and mortality.[191,192] Major clinical consequences of orthostatic hypotension include falls leading to bone fractures, lacerations, and even MI. Patients with CHF and the elderly are at greatest risk for experiencing orthostatic hypotension. The tertiary amines (e.g., amitriptyline, imipramine) may cause more severe orthostatic hypotension than the secondary amines (e.g., nortriptyline, desipramine), and research supports the contention that nortriptyline has the lowest risk for causing orthostatic hypotension among TCAs.[193,194]

There are substantial differences among antidepressants (and antidepressant classes) in regard to overall cardiac safety and arrhythmogenic effects in particular. In general, the SSRIs appear to be relatively safe in patients with a history of arrhythmias or recent MI.[175] In a placebo-controlled investigation, hospitalized patients with unstable cardiac disease were randomly assigned to either sertraline or placebo.[195] Overall, both treatment arms were very well tolerated, and there was actually a lower risk of severe cardiac events reported in the sertraline group (vs. placebo). Retrospective data suggest that SSRIs may be somewhat cardioprotective in depressed patients with heart disease, a benefit that might be explained by their ability to decrease platelet activation.[196,197]

TCAs increase heart rate, probably via intrinsic anticholinergic properties that increase sinus node activity. Clinically, this effect is generally not significant, especially in medically healthy depressed patients.[10,198] However, it may be important in those with underlying conduction disease, coronary artery disease, or CHF. TCAs, even when used at therapeutic dosages for the treatment of depression, decrease premature atrial and ventricular contractions in both depressed and nondepressed patients.[199,200] Because TCAs have a Class 1A antiarrhythmic activity, they have arrhythmogenic activity and thus increase the chances of ventricular arrhythmias and even sudden death. This effect on rhythm and conduction is believed to be related to the inhibitory effects of TCAs on the fast sodium channels and a decrease in Purkinje fiber action potential amplitude, membrane responsiveness, and slowed conduction.[200] Even nortriptyline, which is believed to be one of the safer TCAs in patients with heart disease, was associated with a greater risk for adverse cardiac events than paroxetine.[201] In patients with preexisting conduction defects and in overdose, there is a greater risk for cardiac arrhythmias.[193] Therefore, patients should receive a baseline electrocardiogram (ECG) before therapy, and use in patients with preexisting cardiac conduction abnormalities should be avoided.[10]

Other risks associated with TCAs are a lowering of the seizure threshold. This seems to be worst with clomipramine and maprotiline compared to the others in the class.[10,202,203] This event is particularly risky in high doses, similar to bupropion. If patients are at risk of seizures or have a seizure disorder, SSRIs are much safer and are preferred over the TCAs.[10,202,203] TCAs have also been shown to produce photosensitivity; thus, excessive exposure to sunlight has resulted in severe sunburns. In patients who have had this reaction

---

or whose lifestyle requires frequent contact with sunlight (e.g., lifeguard), switching to another class is recommended.[204]

MONOAMINE OXIDASE INHIBITORS

MAOIs are an alternative for patients who have failed multiple antidepressant trials. MAOIs are believed to relieve depressive symptoms by enhancing the activity of monoamines. This is done by blocking the enzyme monoamine oxidase which breaks down serotonin, dopamine, and NE. This is in contrast to SSRI/SNRI which increases 5-HT and/or NE by preventing its reuptake into the neuron. This may be desirable for refractory cases. Candidates for treatment should be chosen carefully, and MAOIs should be used only by specialist practitioners such as a psychiatrist.

Phenelzine, tranylcypromine, and isocarboxazid were commonly prescribed for the treatment of depression in the 1970s and 1980s, and their usefulness waned primarily because of the risks of serious drug–drug and drug–food interactions.[205] In standard treatment of depression, MAOIs are not recommended except for the treatment of atypical depression where this class appears to have a small efficacy advantage over other classes.[5,10] Data comparing TCAs with SSRIs for atypical depression suggest that the two classes are comparable in efficacy and both are superior to placebo and so SSRIs should still be tried first due to safety concerns.[10,206]

The "cheese reaction," which can manifest as a hypertensive crisis, is so named because it occurred in patients who were taking nonselective MAOIs and ingested foods high in tyramine, a by-product of tyrosine metabolism that is found in certain foods and beverages, such as aged cheese or Chianti wine (Table 86-12). When tyramine is ingested in the absence of an MAOI, it is rapidly metabolized by the MAO enzyme in the GI tract before systemic absorption. In the presence of an MAOI, more tyramine is absorbed and relatively high concentrations of tyramine may be achieved in circulation, resulting in the displacement of NE (and other catecholamines) from presynaptic storage granules. NE surges into the synapse, and as metabolic degradation is inhibited by the MAOI, a profound pressor response is triggered.[207] A slightly safer version of the MAOI class is the once-daily selegiline transdermal. By avoiding the GI tract, selegiline has less effect on the MAO that reduces tyramine from entering the bloodstream via food. Despite the improved safety of selegiline transdermal to oral MAOIs, there still remains a risk of food–drug interactions resulting in hypertensive reactions, particularly at higher doses, and so the FDA has recommended diet restrictions for doses over 6 mg/24 hours. Additionally, there are application site reactions that occur in approximately 35% of patients.[5,208,209] This agent is available in 6, 9, and 12 mg strengths. Selegiline transdermal as well as oral MAOIs are reserved for refractory cases and should be used only by skilled clinicians.[5,209]

Table 86-12

Foods Containing Tyramine

High Amounts of Tyramine[a]
Smoked, aged, or pickled meat or fish Sauerkraut
Aged cheeses (e.g., Stilton, blue cheese)
Yeast extracts (e.g., marmite)
Fava beans
Moderate Amounts of Tyramine[b]
Beer (microbrewed > commercial) Avocados
Meat extracts
Red wines such as Chianti
Low Amounts of Tyramine[c]
Caffeine-containing beverages Distilled spirits
Chocolate

Soy sauce
Cottage and cream cheese
Yogurt and sour cream

[a] May not consume.

[b] May consume in moderation.

[c] May consume.

ADVERSE EFFECTS

Orthostatic hypotension, weight gain, edema, and sexual dysfunction are common during MAOI therapy.[191] As is the case with the TCAs, the nonselective MAOIs can cause clinically significant postural decreases in BP. However, with the MAOIs, the mechanism is believed to be a direct sympatholytic effect because both the lying and the standing systolic BP readings are decreased.[210,211] Phenelzine seems to cause orthostatic hypotension more commonly than does tranylcypromine.[212] Because the orthostatic hypotension appears to be dose-related, a reduction in dosage may be helpful.[213] Sexual dysfunction occurs in up to 20% of patients taking MAOIs but may diminish and disappear spontaneously over time.[214,215] A switch into mania has been reported in up to 10% of patients with a history of bipolar disorder. Therefore, MAOIs should be avoided in this population.[191] Although MAOIs are not known as antimuscarinic medications, some patients complain of anticholinergic-like side effects, including blurred near vision and urinary retention. Dosage reduction may be helpful, but these effects may also diminish over time. The nonselective MAOIs are not associated with proarrhythmic, antiarrhythmic, or contractility effects when used in therapeutic dosages. Like other MAOIs, selegiline can be quite activating, and insomnia is frequently reported.

Several potentially fatal drug–drug interactions occur with nonselective MAOI antidepressants. Like the reaction with tyramine, indirect sympathomimetics such as phenylpropanolamine and pseudoephedrine (common ingredients in over-the-counter cold preparations and diet pills) can cause a precipitous rise in BP that can result in stroke.

The potential for serotonin syndrome with the combined use of SSRIs and MAOI antidepressants or other medications with MAOI effect is well documented. A washout period of at least 14 days should separate the use of an SSRI and an MAOI. Because fluoxetine (and its primary active metabolite norfluoxetine) has a much longer half-life, the recommended washout period is at least 5 weeks after discontinuing this particular SSRI. Caution is advised when any other pro-serotonergic mediations are prescribed such as triptans and tramadol.[140]

CASE 86-2, QUESTION 3: M.G. still had some residual symptoms despite a therapeutic trial of duloxetine 60 mg QAM. An increase to 90 mg resulted in intolerable insomnia. She has had a partial response (approximately 40% reduction in symptoms) but is still impaired by her depression. What are possible next steps?

Antidepressant Augmentation with Non-Antidepressants

Treatment refractory depression (TRD) is considered to be a failure to reach remission with 2 or more antidepressant monotherapy trials that were given at a therapeutic dose and given for an appropriately therapeutic period. Generally, a therapeutic dose is for 4 to 8 weeks. This would not include the time it takes to titrate to a therapeutic dose.[216,217] A common strategy for TRD includes combining antidepressants such as an SSRI with bupropion or mirtazapine, as mentioned previously. Other strategies are augmenting an antidepressant with a medication from another class, or somatic treatments, particularly ECT.[5,10,26,216,217]

There are many options to augment an SSRI/SNRI if the patient has not achieved a full response. Some atypical antipsychotics, lithium and triiodothyronine, all have studies showing efficacy. Buspirone has less robust data but is still recommended.[5,216,217] The use of atypical antipsychotics for the management of treatment-resistant depression has become relatively common among mental health providers due to well-designed and replicated studies. Four atypical antipsychotics (olanzapine in combination with fluoxetine, aripiprazole, brexpiprazole, and quetiapine) have received FDA approval as adjunctive agents with SSRIs or SNRIs for depression that has poorly responded to monotherapy, and others have been reported to be effective as well.[5,216,217] Generally, lower doses of second-generation antipsychotics have been successfully used in trials for depression (vs. schizophrenia), and relatively rapid improvement was evident. Given the significant risk of metabolic side effects that have been reported, clinicians must carefully weigh the risks and benefits of recommending this augmentation strategy prior to maximizing antidepressant monotherapy trials and antidepressant combinatioms.[5,10] It is recommended that nonbehavioral health specialists use caution when using the atypical antipsychotics for poorly responding patients.[182]

One instance where the use of an atypical antipsychotic adjunct is given during the acute phase is with psychotic depression. Patients with psychosis during the depressed episode, as with multiple previous episodes and depression severity, are at greater risk of chronicity and suicidality.[10] Multiple studies have shown benefit of antipsychotic and antidepressant combination better than either monotherapy. Despite the fact that monotherapy may be appropriate for the maintenance phase, it is recommended to start an antipsychotic with the antidepressant during the acute phase and slowly taper off after the persons depression and psychosis remits.[5,10,218] The least preferred antidepressant is bupropion. Its prodopaminergic effect could worsen the psychosis.[10] ECT is also a recommended treatment.[5,10,218]

Lithium's antidepressant properties as an augmenting agent have primarily been conducted with TCAs.[217] Seven of nine antidepressant augmentation trials with lithium have reported positive therapeutic effects, usually within 1 week of achieving steady state dynamics (i.e., 3–7 days of daily dosing).[219] Effective lithium blood levels are generally within the range used to treat bipolar disorder (0.5–1.2 mEq/L). Lithium has a very narrow therapeutic index along with multiple significant drug interactions and should only be used by a clinician skilled in its use.[5]

Triiodothyronine (T_3) also has a long history of use in psychiatric circles for patients exhibiting partial or suboptimal responses to antidepressant monotherapy. Five of six RCTs support the use of T_3 supplementation for antidepressant augmentation, with an average effect size of 0.58 reported.[220] Triiodothyronine, at a dosage of 25 mg/day, can accelerate as well as augment antidepressant response, and superior effects have been reported in female patients, in particular. The response to the thyroid supplementation should be noticeable within 1 to 2 weeks, much like that found when lithium is used to augment therapy. Thyroxine (T_4) may also be effective with typical daily doses of 75 to 100 mcg daily often used. In the STAR*D trials, T_3 was compared to lithium for antidepressant augmentation with citalopram in patients with two previous treatment failures.[221] Remission rates were modest for both agents in this challenging population (24.7% with T_3 vs. 15.9% with lithium), and there was no significant difference between these two therapies.

In the STAR*D trial, augmentation with bupropion was compared to buspirone and both adjunctive treatments showed 30% remission rates.[221] Buspirone may be of benefit to patients with residual symptoms of anxiety, in particular, and titration up to daily doses of 30 to 60 mg daily is often required.[5,182] Stimulants and modafinil have generally shown no benefit on depressive symptoms overall.[182,222] However, they may provide temporary relief from excessive fatigue and somnolence while waiting for the full antidepressant effect of the primary treatments.[5,217]

Because M.G. had a failure to two monotherapies and some response to duloxetine, the option of adding a medication to the SNRI is the next step. Combinations of duloxetine with another antidepressant (mirtazapine or bupropion) or with an atypical antipsychotic are both recommended. Mirtazapine, quetiapine, and olanzapine would help if there is any insomnia and would protect against this side effect if duloxetine were to be increased in the future. Bupropion would possibly worsen the insomnia. Aripiprazole, brexpiprazole, mirtazapine, quetiapine, and olanzapine (least to most) all could cause weight gain worsen cholesterol. Discussing the risks of each option is critical and letting M.G. help decide which choice fits her lifestyle will ensure better adherence. M.G. decided to start aripiprazole 2 mg QAM and will increase her exercising to mitigate the possible weight gain and cholesterol increase.

Pediatric Depression

CASE 86-3

QUESTION 1: A.A. is a 15 year old male who has had a mood and behavior change over the last 6 months. A.A. is a sophomore in high school who averages B's in his classes. He was a member of the varsity lacrosse team, with many friends. Over the last 6 months he has been less involved with his friends to the point that he now doesn't want to go out. After lacrosse season was over he normally would participate in off season lacrosse camps. This year he didn't want to. His grades have dropped as he can't concentrate as well on his school work. He has missed some days of school lately because he doesn't want to get out of bed. Important rule outs are illicit drug use and recent trauma. Both have been ruled out. His medical history is unremarkable except for a 10 pound weight loss since last year, likely due to a poor appetite. His parents are very supportive. What are the recommendations for the treatment of pediatric depression?

Rates of pediatric depression are less than in adults. As a person ages, the risk of depression increases with rates of 0.5% in 3- to 5-year-olds increasing to 3.5% in 12- to 17-year-olds.[10,223] Diagnosing pediatric depression uses the same criteria from the DSM 5 as for adults; however, the interview questions may be slightly different. For example, poor concentration may be mislabeled as procrastination or anhedonia might be described as "being bored."[9] Treatment guidelines do differ compared to adults. One reason for this is that placebo rates are much higher in pediatric studies resulting in the medication not having as dramatic a difference when compared to the difference between placebo and drug in adult studies. Thus, there are many studies where SSRIs had strong response rates but placebo also did and the medication was not considered to be statistically different.[224–226] Due to this high response rate from placebo and the support given by being a subject in a research study, the expert guidelines recommend supportive care and formal talking therapy be the first option for mild-to-moderate depression.[227,228] Medications can be used if symptoms are moderate to severe. Pharmacotherapy options are limited, though, compared to adults. Fluoxetine is FDA-approved down to age 8, escitalopram to age 12. Clomipramine (10 and

---

older), fluvoxamine (8 and older), and sertraline (6 and older) are FDA-approved for obsessive compulsive disorder but not depression. The SNRI duloxetine is approved for 7 years old and above for generalized anxiety disorder, and imipramine is approved for 6 and older for enuresis. To summarize, only two antidepressants are FDA-approved for depression in children although some other antidepressants do have nondepression indications in children.

CASE 86-3, QUESTION 2: The child psychiatrist's initial recommendation is to have A.A. meet with a psychologist. After 4 months of talking therapy A.A. is improved in general but is still having bouts of sadness that prevent him from going to school a couple days a month. It is decided to continue talk therapy but to add a medication. Which medication is the preferred agent?

Unlike adults where all antidepressants are similarly effective, pediatric depression guidelines have recommended that SSRIs particularly fluoxetine and escitalopram be the treatments of choice.[227,228] Fluoxetine's starting dose is 10 mg QAM with a target dose of 20 to 40 mg a day. Escitalopram's starting dose is 5 to 10 mg QAM with a target dose of 10 to 20 mg a day. Interestingly, the separation from placebo increases as the child ages for many of the SSRIs. For example, escitalopram did not statistically differ from placebo in the under 12 year old age group but did so in the adolescent age group.[224,229] Paroxetine is not recommended for depression due to overall lack of efficacy in any age group when studies are combined and a high dropout rate in the younger patient.[224,226] Bupropion, mirtazapine, venlafaxine and duloxetine have recommendations as treatment options but after failures to the SSRIs.[227] TCAs are not recommended primarily due to a high risk of harm being much greater than the small benefit on symptoms.[227,230]

CASE 86-3, QUESTION 3: A.A. is started on fluoxetine 10 mg QAM. What safety monitoring is required when starting a young adult or pediatric patient on an antidepressant?

Generally, the SSRIs are well tolerated in children. One black box warning is for suicidal thinking. As with adults, the clinician needs to monitor for suicidality, but in children there is a doubling of suicidal thoughts, not suicide attempts or completions, from 2% in the placebo arms to 4% in medication arms. It is important to note that actual suicides are much higher in untreated depressed youth compared to those taking antidepressants.[94,231–233] This risk diminishes as age groups increase. For patients over age 24, it is not required to be so vigilant regarding suicidal thinking although many guidelines recommend continuing to monitor throughout the age ranges due to the possibility of disease-related risk. In pediatrics and young adults, the experts recommend the use of antidepressants with the FDA-sanctioned monitoring for suicidal thinking of every week for the first week, every other week for the next 4 weeks, then monthly or as decided by the patient and clinician.[227,234] Talking therapy may have some protection against the side effect of increased suicidal thoughts.[235]

Geriatric Depression

Depression in late life is typically more difficult to recognize than depression in younger adults. Clinicians and patients may inappropriately attribute depressive symptoms to the "aging process" and minimize their significance. In addition, functional expectations are often lowered after retirement, making the degree of impairment difficult to evaluate. Because medical comorbidities are also more common in the elderly, depressive symptoms may be overlooked or misinterpreted in the workup as well.[116,236] In general, the elderly present with the same depressive target symptoms as younger adults, which is reflected in the fact that DSM-5 diagnosis for major depression in adults is not specific for age. However, qualitatively, the presentation of depression among the elderly may be quite different. For instance, older patients are more likely to present with psychomotor retardation and are less likely to acknowledge "depression" per se, preferring instead to dwell on somatic concerns (e.g., poor sleep, low energy, changes in bowel function, bodily aches and pains).[10] They are also much less likely to share or admit suicidal thoughts, and because elderly men have the highest suicide completion rate, an accurate assessment of depression and attendant risks is critical.[10,116,237] In assessing nonspecific behavioral and cognitive symptoms in the elderly, a careful differential diagnosis between medical and other psychiatric disorders is essential because numerous medical illnesses can mimic depressive symptoms. Anemia, malignancies, congestive heart failure (CHF), and endocrine abnormalities may all present in a manner similar to that in depressive illness.

Aging does result in decreased monoamine depletion as well as increased monoamine oxidase activity.[116] One of the more difficult differential diagnoses in this setting involves the distinction of depression from dementias.[238,239] Like depression, patients with dementia may present with apathy, poor memory or concentration, reduced facial expression, and lack of spontaneous interaction. The illnesses are often comorbid, as 30% to 70% of patients with dementia also suffer from major depression.[239] Some experts have suggested, in fact, that new-onset depression in elderly patients may actually be part of a prodrome toward the manifestation of Alzheimer dementia.[239,240] A longitudinal cohort study found that among elderly patients suffering from an acute episode of major depression, 57% were ultimately diagnosed with Alzheimer dementia within the next 3 years.[238] Diagnostically, there are three notable differences between dementia and depression: (a) the symptoms (slow and subtle changes with dementia, rapid with depression), (b) orientation (markedly impaired with dementia, intact with depression), and (c) principal CNS impairment (short-term memory with dementia, concentration with depression).

Drug Selection in the Elderly

A therapeutic trial of an antidepressant in a depressed individual with cognitive impairment may reverse the symptoms of the affective illness and restore functional capacity. Depression-related cognitive dysfunction will also improve to some degree. Moreover, because primary degenerative dementia is largely a diagnosis of exclusion, a successful trial of an antidepressant may help clarify the underlying pathologic condition and is strongly recommended in patients with a positive personal or family history of mood disorders.[241] The overall efficacy of antidepressants in elderly patients is believed to be comparable to that observed in younger subjects, although the response to treatment is somewhat slower (i.e., 6-week therapeutic trial usually warranted).[5] Psychotherapy may be somewhat more effective in the elderly particularly due to the emotional impact of medical comorbidities and neurodegeneration effects as long as there is no dementia hindering talking therapy's effect.[5] Similarly, the comparative therapeutic effects of individual antidepressants do not appear to differ qualitatively between elderly patients and the general population. The selection of antidepressants for geriatric depression is the same as the process for younger patients. The elderly are much more sensitive to side effects compared to the younger patient, and the presence of medical comorbidities and concurrent medications will have a greater influence on antidepressant selection. For example, the anticholinergic effects of TCAs preclude their use in elderly patients particularly if they are suffering from narrow angle glaucoma, chronic constipation, or urinary hesitancy. Anticholinergic impact on memory and the cardiac-related effects such as arrhythmias, orthostasis, and tachycardia are other critical reasons not to use the TCAs in the elderly. As noted previously, the risk of falls from TCAs due to antihistaminic, anticholinergic, and α receptor antagonistic properties is another reason not to use them in the elderly population.

SSRIs are recommended as first line but among this list paroxetine is considered the worst option due to its anticholinergic effects (albeit mild) compared to no effect from the others. SNRIs also have data showing efficacy.[5,10,26] There does seem to be more dropouts with venlafaxine compared to the SSRIs.[5] Although sedating antidepressants such as mirtazapine may serve to promote sleep in depressed patients suffering from insomnia, other geriatric clients may be candidates for more activating medications that can increase energy or enhance alertness (e.g., bupropion).

All antidepressants have a risk of causing the syndrome of antidiuretic hormone secretion (SIADH) with SSRIs being the group with the highest reported cases. Elderly patients, compared to younger patients, are at a much greater risk of this event with some reviews reporting hyponatremia up to 32%.[10,242] As with other medications used in the elderly, the antidepressants should be started at lower initial doses compared to adults.[5,10,116] Titration to a known therapeutic target dose has the best evidence even if the geriatric seems to be responding to a subtherapeutic dose.[5]

Therapeutic Blood Level Monitoring

Attempts to demonstrate an association between plasma concentrations and therapeutic response for SSRIs and SNRIs have been largely unsuccessful. In contrast, the serum concentration of some TCAs correlates well with clinical response. Nortriptyline exhibits a curvilinear effect, whereas imipramine demonstrates a sigmoidal relationship between serum levels and clinical response.[243,244] Maximum benefit of imipramine is usually associated with serum levels of imipramine plus its demethylated metabolite, desipramine, in excess of 250 ng/mL. The relationship between plasma concentration of desipramine and clinical response is less clear, but a linear relationship is likely.[245] The most controversy surrounds amitriptyline; studies have shown a linear relationship, a curvilinear relationship, and no relationship between serum concentration and outcome.[246–248] The APA Task Force on the Use of Laboratory Tests in Psychiatry recommends plasma concentration monitoring of TCAs when patients are elderly, not responding to therapy, nonadherent, experiencing adverse effects, or on multiple medications that may result in a possible drug interaction.[249] Plasma concentrations of imipramine, nortriptyline, and desipramine should be obtained after at least 1 week of a constant dosage when steady state has been achieved. Samples should be drawn 12 hours after the last dose has been administered. Routine therapeutic blood monitoring of other antidepressants is not recommended because information concerning their usefulness is limited; however, serum levels may be useful for evaluating adherence in some patients or ruling out serious toxicities.[250]

Antidepressants and Chronic Pain

CASE 86-4

QUESTION 1: D.C. is a 42-year-old woman with a history of chronic lower back and left leg pain who has noted increased crying spells and a decreased interest in social activities during the course of the last 4 months. She attributes this downturn to the stress she is experiencing as she cares for her disabled mother who recently moved in with her. When asked, she also notes significant decreases in energy and concentration, and difficulties in falling and staying asleep.

In the past, D.C. recalls one previous episode of depression 8 years ago, when she was treated initially with venlafaxine (discontinued due to nausea) and ultimately responded to a course of psychotherapy. Her past medical history is significant for chronic pain from a car accident 7 years ago which continues to bother her on a daily basis (she rates pain at 5 of 10 currently), hypertension and hyperlipidemia. Her current medications include lisinopril 10 mg QAM and atorvastatin 10 mg QHS. In addition, she started amitriptyline 50 mg at bedtime 2 months ago for her insomnia but noticed a 12-pound weight gain and recently discontinued. In the meantime, she has continued to see her therapist on a weekly basis during this time frame.

What considerations may influence treatment selection in this patient with chronic pain? What treatment should be recommended?

There is a strong and complex association between chronic pain syndromes and mood disorders. Epidemiologic investigations report that 50% of patients with chronic pain will satisfy the criteria for a depressive disorder.[251] Anxiety disorders are also commonly reported in this population as well. On the other hand, 65% of individuals with major depression will experience some symptoms of somatic pain, often presenting with pain as their chief complaint. Researchers have theorized that this comorbid phenomenon can be explained by deficiencies in the neurotransmitters serotonin and NE, which influence mood disorders in the prefrontal cortex and limbic system, as well as module pain sensitivity via descending projections down the spinal column. Other theories implicate elevations in cytokine activity, which commonly occur during the course of mood disorders, as well as mediating inflammatory activity occurring within the context of chronic pain.[251,252]

Treatment plans for depressed patients with chronic pain should target both of these conditions in order to achieve optimal outcomes. In regard to the selection of antidepressants, preference is often given to medications that can address both sets of symptoms associated with these comorbid conditions. For instance, antidepressant agents with pain-relieving properties and agents that promote sleep and relieve anxiety are often preferred. Antidepressants that enhance 5-HT and NE (TCAs and SNRIs) have proven to be quite effective for the management of neuropathic pain conditions, in addition to their benefits on anxiety and depression.[5,251,252] SSRIs are much less effective primarily due to the lack of NE enhancement which is critical for analgesia.[5]

Drug interactions are often a major consideration in the selection of antidepressants. For example, the combination of SNRI antidepressants with the analgesic tramadol has been linked to a few case reports of serotonin syndrome, and concomitant use of these agents should be discouraged. Certain opioid analgesics are prodrugs and require metabolic transformation to generate the active species. These analgesics include codeine (metabolized to morphine), hydrocodone (active metabolite: hydromorphone), and oxycodone (oxymorphone), as well as tramadol (o-desmethyl tramadol). Patients who require these medications would benefit from antidepressants that do not effect CYP 450 (Table 86-8).

D.C. meets the criteria for an acute episode of major depression, and medication is clearly indicated. Among the alternatives, SSRIs have not proven to be effective for neuropathic pain. SNRIs and TCAs are effective for neuropathic pain conditions, as well as depression and anxiety. However, there are substantial tolerability and toxicity risks with TCAs not shown with the SNRI class. Additionally, she has experienced significant weight gain with a low-dose TCA (50 mg amitriptyline). An SNRI would be a good choice for the treatment of her depression and chronic pain. Given D.C.'s history of nausea from venlafaxine, an alternate SNRI, such as levomilnacipran or duloxetine, should be initiated. Duloxetine inhibits CYP450 2D6, and this should be taken into consideration if other medication changes are considered in the future.

Summary

Depressive episodes have a significant morbidity impact and can result in mortality, usually via suicide. Treatment has been shown to reduce acute impact and prevent future episodes. All antidepressants are considered generally equal in regard to efficacy. Comorbid drug–disease and drug–drug interactions help identify best first-choice options. Overall, SSRIs are considered the best first choice due to good tolerability, safety in overdose, and low cost. Of these, sertraline and escitalopram may have a slight advantage. Previous treatment successes or failures and family history of medication response are important determining factors when disease and drug issues are not present. Minimal treatment duration should be 6 months after remission has been achieved though many patients will require lifelong pharmacotherapy. Patient education and safety monitoring are critical aspects once the patient enters into treatment. Outcomes for treatment are predictably beneficial with improvements in quality of life and reduction of suicidal events.

Bipolar Disorders

Megan J. Ehret and Charles F. Caley

	CORE PRINCIPLES	CHAPTER CASES
1	Bipolar disorder is a chronic progressive illness that occurs in approximately 4% of the population. It is characterized by recurrent mood episodes of mania and depression. Life stressors, substance use, treatment non-adherence, and medications are common precipitants of these mood episodes.	**Case 87-1 (Questions 1–3)**
2	Manic episodes are characterized by elevated mood, irritability, increased goal-directed activity, inflated self-esteem, poor judgment, and excessive motor activity.	**Case 87-1 (Question 1),** **Case 87-2 (Question 1)**
3	Depressive episodes of bipolar share the same diagnostic criteria as major depressive disorder, including depressed mood, decreased interest, feelings of worthlessness, diminished ability to concentrate, and recurrent thoughts of death.	**Case 87-7 (Question 1)**
4	Valproate, lithium, or atypical antipsychotics are appropriate first-line treatments for acute mania. Depending on the severity of symptoms, these agents may be used alone or in combination.	**Case 87-1 (Questions 4, 5),** **Case 87-2 (Question 1),** **Case 87-5 (Question 2),** **Case 87-6 (Question 1)**
5	Lithium, lamotrigine, quetiapine, lurasidone, or the combination of these agents is appropriate treatments for bipolar depression.	**Case 87-7 (Question 1)**
6	Maintenance treatment of bipolar disorder is imperative to prevent disease progression. The standard of practive is to continue the acute-phase treatment with gradual simplification toward monotherapy, if possible, with lithium, lamotrigine, valproate, or atypical antipsychotics.	**Case 87-5 (Question 1),** **Case 87-8 (Questions 1, 2)**
7	Medications used to treat bipolar disorder have a wide range of adverse effects that may impact adherence. The history of response, patient preference, and long-term tolerability profile are important considerations when selecting an agent. Therapeutic blood level monitoring, as well as laboratory monitoring for adverse effects, is commonly required for certain medications.	**Case 87-1 (Questions 6–8),** **Case 87-2 (Questions 1–8),** **Case 87-3 (Questions 1, 2),** **Case 87-4 (Questions 1, 2)**
8	Non-pharmacologic treatments including electroconvulsive therapy (ECT) and herbal supplements are important considerations for the treatment of bipolar disorder.	**Case 87-8 (Questions 3, 4)**

INTRODUCTION

Bipolar disorder (BD), once known as manic depression, is a severe life-threatening psychiatric condition that is commonly misdiagnosed and too often insufficiently treated.[1,2] BD is associated with high rates of healthcare utilization, suicidal behavior, and use of public assistance.[3] The global burden of BD is immense, exceeding many chronic diseases including human immunodeficiency virus, diabetes mellitus, and asthma.[4]

Epidemiology

Using DSM-IV-TR criteria, the 12-month prevalence of bipolar I disorder is estimated to be 0.6%; bipolar II disorder is marginally more common at 0.8%.[5] The prevalence rate for the bipolar spectrum of illnesses, which include bipolar I, bipolar II, and subthreshold BD (i.e., Bipolar Disorder Not Otherwise Specified [NOS]), is 4.4%.[6] Bipolar I and II are more common in women than in men, whereas subthreshold illness predominates in men.[6] The familial nature of BD has been well established with an

11-fold increased risk in first-degree relatives.[7] Twin studies add further support to the genetic linkage. Goodwin and Jamison reported a 63% concordance rate (rate of illness in co-twin of affected proband) for monozygotic twins compared with 13% for dizygotic twins.[7]

The estimated total U.S. economic burden of BD between 1991 and 2009 was reported to be $151 billion.[8] Direct costs, such as hospitalization, outpatient visits, and medications, accounted for 20% of the total. The remaining 80% was attributable to indirect costs such as lost productivity by patients and caregivers.

The mean age of onset of symptoms for the bipolar spectrum of illnesses is 21 years.[6] Bipolar I is the earliest in onset at age 18, compared with bipolar II at age 20 and subthreshold BD occurring at age 22.[6] Approximately 20% to 30% of new cases occur in children between 10 and 15 years old.[9,10] Late-life onset of BD is rare. After age 60, there is a sharp reduction in the new onset of BD; therefore, a presentation of mania at this age should alert the clinician to an underlying medical problem as the possible cause.[11]

Patients may present initially with any affective episode, but it is important to note that 75% of patients report having had multiple episodes of depression before the development of a manic episode.[9] Not surprisingly, misdiagnosis (primarily as major depressive disorder) is common, occurring in roughly 70% of patients.[9] By some accounts, one in four patients visit as many as five physicians before an accurate diagnosis is made. A significant contribution to misdiagnosis is the underreporting of manic symptoms, which are not considered to be particularly problematic by patients.[9]

BD is a recurrent illness; single episodes of mania, unrelated to BD, occur in fewer than 10%.[12] Most patients with BD suffer multiple episodes of mania, hypomania, or depression separated by periods of euthymia (stable mood) throughout the course of their lives. In the majority, mania occurs just before or immediately after a depressive episode.[12] There may be a 5- to 10-year period from the onset of illness until the first hospitalization or diagnosis of BD.[11]

The course of illness is characterized by the type of episode(s), duration of euthymic intervals, frequency of relapse, severity of episodes, and predominant syndrome (mania, hypomania, or depression). These factors do not remain fixed throughout an individual's illness. For instance, individuals may experience episodes of dysphoria and depression before ever experiencing hypomania or mania. Often, the euthymic interval and cycle length decrease with additional episodes. With time, a course of alternating recurrent depression interspersed with manic or hypomanic episodes and no intervening euthymic periods can develop.

A specifier of BD, termed rapid cycling, occurs in both bipolar I and bipolar II disorder and is defined as a patient experiencing four or more mood episodes per year. Rapid cycling is common, occurring in 20% of cases; women are more often affected than men.[13] The rapid cycling type of BD is often refractory to conventional treatment and carries significant morbidity and mortality because of rapid changes in mood states.

The prognosis, even for treated BD, is concerning, with 73% experiencing a recurrent mood episode within 5 years. Furthermore, nearly half of patients continue to have significant mood symptoms between episodes, whereas less than 20% are euthymic or have minimal symptoms.[14]

Pathophysiology

BD is a complex disease involving developmental, genetic, neurobiologic, and psychological factors.[15] Neuroimaging studies have demonstrated neurochemical, anatomic, and functional abnormalities in those with a diagnosis of BD.[16] Recent studies have demonstrated that altered synaptic and circuit functioning accounts for mood and cognitive changes rather than the previous theory of dysfunction of individual neurotransmitters.[17] Environmental, or psychosocial, stressors, immunologic factors, and sleep dysfunction have been associated with BD and can negatively influence the course of illness.[18–22]

Clinical Presentation

Risk factors for BD include family history of mood disorders, perinatal stress, head trauma, environmental factors (including circadian rhythm disorders), and psychosocial and physical stressors. A recent systematic review of 16 published reports with varying study designs suggested that early phases and suspected precursor states for those who develop BD include: early-onset panic attacks and disorder, separation anxiety, generalized anxiety disorders, attention deficient hyperactivity disorder, and conduct symptoms and disorder.[23]

A manic episode usually begins with a change in sleep patterns along with mood elevation. Presenting symptoms include talkativeness, lack of sleep, and bursts of energy during which projects are begun but rarely completed. Mania often is characterized by thought disturbances exhibited by “flight of ideas” (rapid speech that switches among multiple ideas or topics) and grandiose delusions (false beliefs of wealth, special powers, knowledge, abilities, importance, or identity). The behavior of manic patients is characterized as being intrusive, loud, intense, irritable, at times suspicious, and even challenging. Patients often exercise poor judgment, which may include spending large sums of money in business deals that ultimately fail, becoming sexually promiscuous, using substances of abuse, or failing to obey laws.

The symptoms of mania usually develop gradually over the course of several days to more than a week and are defined in three stages.[24] Stage I is characterized by euphoria, irritability, labile affect, grandiosity, overconfidence, racing thoughts, increased psychomotor activity, and an increase in the rate and amount of speech. This stage corresponds to an episode of hypomania. Stage II features increased dysphoria (a feeling of extreme discomfort and unrest), hostility, anger, delusions, and cognitive disorganization. This stage corresponds to acute mania. Many patients progress no further than this stage. Others may proceed to stage III, in which the manic episode progresses to an undifferentiated psychotic state. Individuals in stage III experience terror and panic, their behavior is bizarre, and psychomotor activity is frenzied. They may experience hallucinations. What were once simply disorganized thoughts become incoherent; disorientation to time and place occurs. Just as the manic episode gradually builds, it often declines in a gradual manner. Psychotic symptoms usually resolve first, whereas irritability, paranoia, and excessive behavior persist. Remaining symptoms such as talkativeness, seductiveness, and dysphoria slowly decrease with time.

Depressive episodes of BD share the diagnostic criteria with unipolar depression; however, the presentation of bipolar depression has some distinguishing features. In particular, bipolar depression (type I specifically) is more likely to be associated with mood lability, psychotic features, psychomotor retardation, and comorbid substance use.[25] This contrasts with unipolar depression, which is more likely to be associated with anxiety, agitation, insomnia, somatic complaints, and weight loss.[25]

Mixed states appear to be common and could represent a more severe phase of bipolar illness. These episodes have been associated with a younger age of onset, more frequent occurrence of psychotic symptoms, major risk for suicide, higher rate of comorbidities, and longer time to achieve remission.[26–28]

A review by Salvatore et al.[29] identified three important presentations of mixed states: manic stupor, agitated depression, and unproductive mania. Manic stupor, "the most important of the mixed states," is characterized by mood elevation with a deficit in psychomotor activity (stupor) and slowed thoughts.[29] Agitated depression occurs when depressed mood is experienced with psychomotor activation and flight of ideas. Unproductive mania consists of mood elevation, psychomotor activation, and thought retardation. Mixed states can occur abruptly or serve as a transitional phase to a depressed or manic episode. The duration may be short-lived, lasting only days, or may take on a chronic course of weeks to months.

Patients with BD have higher rates of mortality from both natural and unnatural causes. Higher rates of natural deaths largely result from cardiovascular disease.[30] Mortality due to cardiovascular disease in BD has been estimated to be twice as frequent as the general population.[31–33] Rates of cerebrovascular disease, coronary heart disease/acute myocardial infarction, and cardiac arrest/ventricular fibrillation are all estimated to be increased in BD patients.[33] Suicide (more likely during depressive and mixed states) and excessive risk-taking behaviors (more likely to occur during manic or hypomanic episodes) also contribute to the high mortality rate. Suicidal behavior is a complex issue that likely depends on both environmental circumstances and risk factors inherent to BD, and current evidence regarding suicide risk is likely confounded by multiple risk factors.[34] Lifetime risk for an attempted suicide is reported to occur in as many as 25% to 50% of patients with BD, while the lifetime risk of a completed suicide may be as high as 17% to 19%.[35] The most rigorously determined estimate for completed suicide in BD reports rates of 7.8% in men and 4.8% in women.[36] Previous suicide attempts and the presence of hopelessness are primary risk factors for completed suicide.[37] Non-lethal suicidal behavior also has risk factors that are multifactorial and include a family history of suicide, younger age at onset, greater severity of mood episodes, the presence of mixed episode, rapid cycling, comorbid psychiatric conditions, and substance use.[37] Fortunately, overall mortality as well as deaths owing to suicide or cardiovascular disease are significantly reduced when BD is adequately treated.[14]

Approximately 42% of patients with BD have comorbid substance use disorders.[6] The estimated lifetime prevalence of a comorbid substance use disorder in BD patients is 40% for bipolar I and 20% for bipolar II.[38] Comorbid alcohol use in BD is estimated at 50%, while comorbid cannabis use is estimated at 30%.[39,40] Those with rapid cycling and dysphoric mania have the highest rates of substance use.[41] BD becomes difficult to treat in the face of active substance use. Constant intoxication and withdrawal not only impact the course of BD but masquerade as mood episodes. Symptoms are highly recurrent, and treatment resistance is common, as is violence and suicidal behavior.[42] The best outcome is achieved with aggressive simultaneous management of both BD and the concurrent substance use disorder.

Individuals with BD are likely to experience stress and upheaval in many areas of their lives, including relationships, employment, and finances. Of patients with BD, 88% have been hospitalized once and 66% at least 2 times.[43] Divorce rates in those with BD are two- to threefold higher than those found in non-affected populations. Patients often report having poor relationships with family members, and nearly 75% report that their family members have a limited understanding of BD.[9] Employment problems may result from bizarre, inappropriate, or unreliable behavior. In one study, 60% of patients reported being unemployed, 88% felt the disease affected how well they performed at work, and 63% felt that they were treated differently from their peers.[9] Financial and legal problems are tied to excessive spending, involvement in schemes, substance abuse, and risk-taking behavior.

Diagnosis

Mood disorders like BD are diagnosed using the criteria established in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5).[12] Discrete periods of mood disturbance associated with BD are defined as manic episodes, hypomanic episodes, or major depressive episodes with various specifiers including mixed features and rapid cycling.

Manic or hypomanic episodes (Table 87-1) are periods of abnormally and persistently elevated, expansive, or irritable mood and persistently increased goal-directed activity or energy.[12] Hypomanic episodes are less intense than manic episodes, but are severe enough to impair functioning (self-care, occupational, social), complicate a medical condition, result in psychotic features, or require hospitalization.[12] Although manic and hypomanic episodes are characteristic symptoms of BD, it is depressive episodes that predominate and are ordinarily the initial presenting symptom.[44,45] Major depressive episodes share the same criteria with major depressive disorder (see Chapter 86, Depression).[12]

A person who has experienced one or more manic episodes with or without a depressive episode is diagnosed as having bipolar I disorder. An individual who has experienced one or more episodes of both hypomania and depression (without a history of manic episodes) is diagnosed as having bipolar II disorder.[12]

Table 87-1

DSM-5 Criteria for a Manic Episode

1. A distinct period of abnormally and persistently elevated, expansive, or irritable mood, and persistently increased goal-directed activity or energy lasting ≥1 week (or of any duration if hospitalization is necessary).[a]
2. During the period of mood disturbance and increased energy or activity, at least three of the following symptoms have persisted (four if the mood is only irritable) and have been present to a significant degree:
    - Inflated self-esteem or grandiosity
    - Decreased need for sleep (e.g., feels rested after only 3 hours of sleep)
    - More talkative than usual or pressure to keep talking
    - Flight of ideas or subjective experience that thoughts are racing
    - Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
    - Increase in goal-directed activity (either social, at work, at school, or sexually) or psychomotor agitation
    - Excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., th person engages in unrestrained buying sprees, sexual indiscretions, or foolish business investing)
3. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usua social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.
4. The symptoms are not caused by the direct physiologic effects of a substance (e.g., a drug of abuse, a medication, or other treatment) or a general medical condition (e.g., hyperthyroidism).

[a] Criteria for a hypomanic episode are identical to a manic episode; however, the symptoms need only be present for 4 days and are not severe enough to cause marked impairment in social or occupational functioning, necessitate hospitalization, or for psychotic features to be present.

Manic-like or hypomanic-like episodes that are clearly caused by somatic antidepressant treatment (e.g., medication, electroconvulsive therapy, light therapy) should not count toward a diagnosis of bipolar disorder.

Source: American Psychiatric Association. Mood disorders. In: American Psychiatric Association, ed. Diagnostic and Statistical Manual of Mental Disorders. 5th ed. Text Revision. Washington, DC: American Psychiatric Association; 2013;123:124.

The diagnosis of a cyclothymic disorder is for a person who has experienced at least 2 years of both hypomanic and dysthymic periods without ever fulfilling the criteria for an episode of mania, hypomania, or major depression.

The DSM-5 also uses a series of descriptors called specifiers to further characterize the course of illness and the most recent type of episode experienced by the individual. Recent episodes are first classified as hypomanic, manic, or depressed. A mixed specifier is diagnosed when a patient meets criteria for either manic or hypomanic episode with at least 3 depressive symptoms being present during the current or most recent episode of mania or hypomania or when a patient meets criteria for depressive episode with at least 3 manic or hypomanic symptoms being present during the current or most recent episode of depression.[12] They may be described further in terms of severity (mild, moderate, severe), the presence of psychotic features (in partial or full remission), with or without catatonic features, or with peripartum onset. Other specifiers convey information regarding the pattern of illness. For example, some individuals experience major depressive episodes at a characteristic time of the year (usually the winter) or switch from depression to mania during a particular season, “with seasonal pattern”. The rapid cycling specifier applies to those who experience at least four mood episodes in the previous 12 months that meet criteria for manic, hypomanic, or major depressive episode.[12]

Overview of Treatment

During the previous 15 to 20 years, several treatment guidelines have been published. Recent treatment guidelines have been published by the Department of Veterans Affairs (2010), the British Association for Psychopharmacology (2016), Canadian Network for Mood and Anxiety Treatments (CANMAT), World Federation of Societies of Biological Psychiatry (WFSBP), and the Harvard South Shore Program (2010/14).[35,46–50] The reader is advised that published efficacy research is categorized by bipolar type (I vs. II), mood episode (manic vs. mixed vs. depressed), and treatment phase (acute vs. maintenance). As such, treatment guidelines may reflect these specifiers, depending upon their date of publication. Additionally, there is often an uneven amount of published evidence supporting treatment recommendations in these clinical categories.

The reader is advised that when considering the published efficacy research and guidelines for bipolar disorder, it is necessary to first consider acute versus chronic treatment, and then manic versus depressed episode.

The goals of treatment across the phases of illness are numerous, including the control of acute symptoms, achieving symptomatic remission, returning to a normal level of functioning, prevention of relapses, and prevention of suicide.[11] Both the acute treatment of manic and depressive episodes and the maintenance treatment for prevention of future episodes require individualization of therapy. Treatment decisions should take into account presenting symptoms, medication history, patient preference, and comorbid medical or substance use conditions.

Initial treatment for acute hypomanic or manic episodes should be with one of the well-established antimanic agents such as lithium, valproate (VPA), or one of several atypical antipsychotics (AAP). During episodes of mania, short-term adjunctive use of benzodiazepines is often useful to reduce agitation and promote sleep.[11] In the case of severe manic symptoms or in those only partially responsive to an adequate trial of monotherapy (generally 1–2 weeks), a two-drug combination of lithium, valproate, or an AAP is recommended.[46] Carbamazepine (CBZ) and a typical antipsychotic, alone or in combination with a preferred antimanic drug, are potential alternatives. For treatment-resistant cases, electroconvulsive therapy (ECT), clozapine, and a three-drug combination of lithium plus an anticonvulsant (CBZ or VPA) plus an AAP are recommended. When drug combinations are used, the individual agents should be from different medication classes. Lamotrigine is not recommended for the treatment of acute mania.

In the case of acute mixed states, VPA or an AAP is preferred over lithium because of its poor efficacy. If monotherapy with VPA or an AAP is ineffective or undesirable, then a combination of the two is advised.

Medications for the treatment of bipolar depression ideally produce an acute antidepressant response and prevent future depressive episodes, all while not inducing mania or mood cycling. Long-term tolerability is critical because of the chronic recurrent nature of depressive episodes in BD. First-line treatment options vary based on the chosen guideline, but it includes choices of lithium, lamotrigine, lurasidone, olanzapine or quetiapine monotherapy or lithium or valproic acid or olanzapine with a selective serotonin reuptake inhibitor (SSRI), lithium plus valproic acid, or lithium or valproic acid plus bupropion.[47–52] Subsequent treatment trials again vary on guideline, but include different combinations of the above choices. Additional options include adjunctive modafinil or other antidepressants. Third-line treatment includes carbamazepine, ECT, or lithium plus pramipexole or a monoamine oxidase inhibitor (MAOI) or a tricyclic antidepressant (TCA). Readers are referred to individual guidelines for complete details.

Maintenance treatment of BD should include continuing the acute-phase treatment while periodically simplifying and moving toward monotherapy with lithium, VPA, or lamotrigine if possible. Many AAPs are effective in maintenance treatment of BD; however, they must be used cautiously because of the long-term risk of metabolic and neurologic complications.[48] Olanzapine, quetiapine, aripiprazole, and long-acting injectable risperidone are effective. Regardless of the regimen selected, medication adherence is critical to long-term recovery. Patients and caregivers must be actively engaged in discussing causes of non-adherence, including ambivalence, adverse effects, lack of insight, and a strong desire to achieve the euphoria and energy of manic episodes.[11] Patients should also be advised to maintain regular patterns of daily activities, a consistent sleep–wake cycle, meals, exercise routines, and other schedules to promote stability.

CLINICAL ASSESSMENT

Clinical Presentation and Diagnosis

CASE 87-1

QUESTION 1: T.R. is a 25-year-old man, accompanied to the clinic by his wife, A.R. She called the clinic before bringing him in and reported much of the following information. T.R. states that he was doing well until about 3 weeks ago, when he returned home from a crab fishing trip where he works for the winter months. Given the stress of the job, he borrowed some “nerve pills” from his fellow co-worker. Since then, T.R. has been acting increasingly “wild.” He has been staying up later at night and often bursts into the bedroom at 2 or 3 AM and loudly awakens A.R. Sometimes, he presents her with expensive gifts, which they cannot afford. He often jumps on the bed and starts singing her love songs in a loud voice. A.R. notes that T.R. then almost always demands sex, after which he sleeps for 2 to 3 hours and then loudly gets up and leaves the house.

During the last several weeks, he was noted to be driving his car recklessly and well beyond the speed limit. The police have

---

pulled him over several times and given him multiple tickets for not only speeding, but for running red lights and passing on the double yellow lines. Last week, when his boss called to express concern about his behavior, T.R. said he was quitting his job. He wrote an rambling, disorganized resignation note, which was at least 10 pages long, called an overnight air delivery service to send the note to his employer (who is located only 3 miles from his home), and then left the house before the driver arrived to pick it up. T.R. returned several hours later with a brand new car and wearing an expensive new suit, red cowboy boots, and a bright green hat with a large feather. He told A.R. that he had a new job, which was going to make him a millionaire. Last night, she found a large sum of money in his pants pocket when emptying the clothes hamper. He did not come home at all, but he called her at 4 AM to tell her to pack for Dallas, where he was going to become the new head coach of the professional football team.

On arriving at the clinic, T.R. insists, “I don’t need no doc. I am supercalifragilistic!” He then bursts into song. He is dressed flamboyantly but needs a shave and shower. He gives the examiner (a stranger) a bear hug and has trouble sitting still, listening, or allowing others to talk. His speech is pressured and loud; he often fails to complete sentences or communicate entire ideas, and he is rhyming and punning. His mood obviously is elevated, but he becomes increasingly irritable throughout the examination. He is oriented to person and place, but thinks it is tomorrow. Intelligence seems average. When asked to interpret a proverb, T.R. becomes angry and throws a chair across the room. How is T.R.’s presentation consistent with the diagnosis of a manic episode?

The hallmark of a manic episode is changes in mood, behavior, cognition, and perception (Table 87-1).[24] T.R. demonstrates an elevated mood. He is exuberant and notes how great he feels. Nevertheless, manic patients often demonstrate lability in their mood, and they may become irritable and easily frustrated, especially when challenged. In this case, T.R. becomes irritable and resentful when questioned by the examiner. His quick displays of anger further demonstrate the volatility of his mood.

T.R. displays behavior and speech typical of acute mania. He has a reduced need for sleep, behaves recklessly, and is overactive. His speech is pressured, loud, and full of rhymes and puns, and he sings to express his emotions and skips from topic to topic reflecting a flight of ideas. Behavior often is characterized as being excessive. T.R. dresses flamboyantly, hugs his examiner, writes an unnecessarily lengthy letter of resignation, seeks an overnight courier service for local delivery, and presents his wife with lavish gifts.

Delusions are often present in acute mania and are grandiose or religious in nature and deal with inflated abilities, self-importance, wealth, or special missions in life. T.R. makes unrealistic comments about his money-making schemes, his singing ability, and his position as the coach of a professional football team.

Patients with acute mania are often disorganized and do not complete tasks. They tend to skip from idea to idea and scheme to scheme. In this case, T.R. neglects his hygiene and neglects sending out his resignation letter.

Precipitating Factors

CASE 87-1, QUESTION 2: What factors make T.R. vulnerable to the occurrence of a manic episode at this time?

T.R. is at the age at which his disorder would likely first manifest itself. In addition, manic episodes are often precipitated by psychosocial and recurring life stressors.[7] Working long hours with reduced sleep may have served as a predisposing factor for the development of a manic episode.

Table 87-2

Selected Drugs Reported to Induce Mania[53–74]

Anticonvulsants	Gabapentin, lamotrigine, topiramate
Antidepressants	Monoamine oxidase inhibitors, TCAs, SSRIs, SNRIs, bupropion, nefazodone, trazodone, mirtazapine, vortioxetine
Antimicrobials	Clarithromycin, ofloxacin, cotrimoxazole, erythromycin, isoniazid, metronidazole, zidovudine, efavirenz
Antiparkinsonian drugs	Levodopa, amantadine, bromocriptine
Anxiolytics/hypnotics	Buspirone, alprazolam, triazolam
Atypical antipsychotics	Aripiprazole, olanzapine, quetiapine, risperidone, ziprasidone
CNS stimulants	Caffeine, cocaine, methylphenidate, amphetamine
Drugs of abuse	Marijuana, PCP, LSD
Endocrine	Corticosteroids, thyroid supplements, androgens
Herbals	Saint-John's-wort, SAMe, ma-huang, omega-3 fatty acids, tryptophan
Sympathomimetics	Ephedrine, phenylpropanolamine, pseudoephedrine, phenylephrine
Miscellaneous	Cimetidine, tramadol, sibutramine

CNS, central nervous system; LSD, lysergic acid diethylamide; PCP, phencyclidine; SAMe, S-adenosyl-L-methionine; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

A variety of medications and clinical states can induce or precipitate manic episodes (Table 87-2).[53–74] The drugs that most commonly precipitate mania affect monoamine neurotransmitters, such as antidepressants and stimulants.[53] Corticosteroids, anabolic steroids, isoniazid, levodopa, caffeine, and over-the-counter stimulants can induce or aggravate mania.

CASE 87-1, QUESTION 3: If the "nerve pills" borrowed by T.R. were antidepressants, could they have contributed to the development of his manic episode?

Antidepressants are commonly prescribed for patients with bipolar depression

(35%–40%).[47] Their use is controversial though with criticisms that they lack efficacy or that they destabilize mood and can cause a switch to mania. All of the major classes of antidepressants including monoamine oxidase inhibitors, tricyclic antidepressants (TCAs), SSRIs, and SNRIs have been associated with precipitating mania in patients with BD.[54] Despite this risk, up to 50% of patients with BD are treated with antidepressants of which only half are receiving a concurrent mood stabilizer.[75] There are numerous case reports of mania or hypomania with antidepressant treatment, but few controlled studies, making it difficult to make comparisons across antidepressant classes.[76] See Case 87-7 for complete details of the use of antidepressants in bipolar depression.

A comparison of the monoamine oxidase inhibitor, tranylcypromine, and the TCA, imipramine, found a similar rate of treatment emergent mania (21% and 25%, respectively).[77] A meta-analysis found a higher "switch" to mania rate for TCAs (11%) than for SSRIs (4%).[78] A controlled trial with bupropion,

---

sertraline, and venlafaxine (all in combination with a mood stabilizer) found an overall switch rate of 19% during acute treatment and 37% during the continuation phase of the study with no difference among agents.[79] Antidepressants may also cause cycle acceleration, which effectively decreases the time between mood episodes. The risk for cycle acceleration may be heightened for patients who experience manic or hypomanic symptoms on antidepressants despite receiving antimanic treatment concurrently.[80] Other recent literature has suggested that adjunctive antidepressants to mood stabilizers versus placebo are not associated with an increased efficacy or with increased risks of treatment emergent affective switches.[81] In the case of T.R., an antidepressant may have precipitated the manic episode or shortened his cycle, moving him into an episode of mania from a preexisting state of depression or euthymia.[82] Any patient presenting with an acute manic episode should have a review of medications completed to determine the risk of continuing antidepressant medications.[35]

Current guidelines state that the dual-action monoamine reuptake inhibitors carry a greater risk of precipitating a switch to mania than single action drugs. Additionally, they state that antidepressant medications medications appear unlikely to induce mania when used in combination with a drug for mania.[47]

TREATMENT OF ACUTE MANIA

CASE 87-1, QUESTION 4: Why does T.R. require treatment?

Manic episodes have a number of severe complications. Left untreated, severe mania can result in confusion, fever, exhaustion, and even death. The impairment in judgment, the excesses, and the risk-taking that occur during manic episodes may be devastating. Detriments to relationships, careers, and finances and physical harm or loss of life may occur. Manic individuals may engage in illegal activities or behave in a manner that result in a violation of the law. T.R. drives recklessly; may have lost his job; spends excessive amounts of money on gifts, clothing, and automobiles; and plans to participate in a variety of money-making schemes. He has acquired a great deal of cash suddenly, perhaps from withdrawing all of his family's savings or from some type of illegal enterprise. Manic patients may engage in risky sexual encounters, leading to infection with sexually transmitted diseases including human immunodeficiency virus. Alcohol and substance abuse are common and may exacerbate or even precipitate mood episodes. Irritability, such as that demonstrated by T.R., can lead to episodes of violence, resulting in potential harm to the patient or to others. The goals of treatment are to reduce the severity and duration of the current mood episode as well as to prevent recurrence of future episodes.

Valproate (Divalproex Sodium, Valproic Acid)

CASE 87-1, QUESTION 5: What is the appropriate treatment for T.R.'s acute manic episode?

Depending on the type and severity of mania, first-line treatment involves selecting from lithium, VPA, AAPs, or a combination of these agents.[46–50] If psychosis is present, an AAP would be an appropriate choice either as monotherapy or in combination with a mood stabilizer. VPA is an ideal choice for T.R. considering the rapid onset, tolerability, and the established efficacy of this agent for preventing future mood episodes.[83–85]

DOSING AND MONITORING

CASE 87-1, QUESTION 6: VPA was chosen for the management of T.R.'s mania. How should VPA be initiated, and what baseline tests are necessary? How will T.R.'s response to therapy be monitored?

The initial dose of VPA for T.R. should be 250 mg 3 times per day.[11] The dosage should then be increased by 250 to 500 mg every 2 to 3 days to obtain steady-state serum VPA levels between 50 and 125 mcg/mL or a maximum dosage of 60 mg/kg/day.[86] An alternative strategy is to use an oral loading dose regimen of 20 to 30 mg/kg/day given on a 3 times a day schedule during an acute episode of mania. This approach has been used during inpatient management and may result in a more rapid onset of effect.[87] VPA levels of 50 mcg/mL are the minimum threshold with higher concentrations offering greater benefit. In fact, those exceeding a serum concentration of 84 mcg/mL by the third day of treatment may have greater early symptom improvement.[88] A pooled analysis demonstrated a linear relationship between serum concentration and efficacy with the greatest improvement found in patients with VPA levels in excess of 94 mcg/mL.[89] VPA levels greater than 125 mcg/mL are more often associated with side effects and should be avoided.[83]

Before VPA is initiated, baseline laboratory tests, including a complete blood count (CBC) with differential and platelets, and liver function tests should be measured. T.R.'s baseline weight and neurologic status should be recorded. In premenopausal women who have not undergone surgical sterilization, a baseline pregnancy test is warranted since VPA is a known teratogen. Attention should be given to any medications that might be administered concurrently. Interactions with aspirin, lorazepam, phenytoin, phenobarbital, lamotrigine, rifampin, warfarin, felbamate, and CBZ are cited frequently (also see Chapter 60, Seizure Disorders).

VPA should decrease the severity and duration of T.R.'s current manic episode, decrease the frequency of subsequent episodes, and increase his time spent in a euthymic state. Once treatment has started, T.R. should be monitored for response of his initial target symptoms, including grandiosity, decreased need for sleep, pressured speech, distractibility, and impulsivity. Initial symptom improvement with VPA can be expected in approximately 5 days.[89]

Side Effects

CASE 87-1, QUESTION 7: What are the potential side effects of VPA therapy? How should T.R. be monitored for these possible effects?

T.R. should be monitored for potential dose-related adverse reactions of VPA including various gastrointestinal complaints (nausea, diarrhea, dyspepsia, anorexia), sedation, ataxia, tremor, transaminase elevations, and thrombocytopenia. Reducing the dosage, changing to an extended-release preparation,[90] or administering an antacid or histamine H2-antagonist may mitigate gastrointestinal complaints. Central nervous system effects such as ataxia and sedation may respond to dosage reduction, although sedation may resolve with continued treatment. If a tremor is bothersome or interferes with the patient's functioning, a dosage reduction or change to the extended-release preparation may provide relief.[86] Small elevations in transaminases are considered benign; however, VPA should be discontinued if elevations are more than 2 to 3 times the upper limit of normal.[91]

Weight gain occurs in up to 20% of patients receiving VPA.[83] The increase in body weight is particularly distressing to some patients and may contribute to medication non-adherence. Weight gain has been associated with VPA at different concentrations, so a dosage reduction may not be helpful.[83,92] In women, VPA

---

has been associated with the development of polycystic ovary syndrome.[93] Core features of polycystic ovary syndrome include oligomenorrhea and hyperandrogenism, which develop in about 10% of women with BD taking VPA. Alopecia occurs in 0.5% to 12% of patients and may improve with dose reduction.[94]

There are several reports of VPA-induced hyperammonemic encephalopathy in psychiatric patients.[95,96] Patients presenting with coma or mental status changes should have serum ammonia and liver functions tests ordered. If VPA-induced hyperammonemic encephalopathy is suspected, then VPA should be discontinued. Other serious adverse events with VPA include fulminant hepatic failure, agranulocytosis, and pancreatitis. All of these adverse events require immediate discontinuation of therapy.

In January 2008, the U.S. Food and Drug Administration (FDA) issued a warning to healthcare professionals about the potential for an increased risk of suicidality associated with antiepileptic drugs (AEDs), including VPA. For its analysis, FDA used data from 199 randomized clinical trials of 11 AEDs involving 43,892 study participants with either psychiatric or neurologic disorders. In the "Warnings and Precautions" section of AED product labels, it is stated that the risk of suicidality for those treated with AEDs during clinical trials was approximately twice that of placebo treatment (0.43% vs. 0.24%; adjusted relative risk = 1.8, 95% CI = 1.2, 2.7; number needed to harm = 530). In these clinical trials, there were a total of four suicides in AED-treated patients, and zero suicides in placebo-treated patients. As a result, practitioners are advised to inform patients and caregivers to be vigilant about the emergence or worsening of signs and symptoms of depression or mood/behavior changes, especially if they involve thoughts or behaviors centered on self-harm when patients receive AED treatment.[97]

Once VPA therapy is initiated, liver function tests, VPA serum levels, and CBCs with differential and platelets should be monitored at least monthly for the first 3 months and every 3 to 6 months thereafter.[11] Body weight should also be determined at baseline and monitored monthly during therapy.

CASE 87-1, QUESTION 8: T.R. was titrated to a total daily VPA dosage of 2,500 mg/day and determined to have a steady-state plasma concentration of 95 mcg/mL after 1 month of treatment. A routine CBC with differential and platelet count was ordered at this time, and the following data were reported:

Red blood cells, 5.2 × 106/μL
Hemoglobin, 14.5 g/dL
Hematocrit, 43%
White blood cell count, 8.5 × 103/μL
Neutrophils, 59%
Lymphocytes, 27%
Monocytes, 6%
Eosinophils, 2%
Basophils, 0.5%
Platelets, 75 × 10^3/μL

How should T.R.'s VPA-induced thrombocytopenia be managed?

VPA-induced thrombocytopenia occurs in 18% of patients and is associated with female gender and higher VPA levels (>100 mcg/mL in women and >130 mcg/mL in men).[98] Clinicians should educate patients to look for signs such as easy bruising or bleeding. In most patients, thrombocytopenia is asymptomatic and responds to a lowering of the VPA dosage; complete discontinuation of the drug is usually unnecessary.[99] T.R.'s dosage should be reduced, and his platelet count should be monitored closely. In addition, he should be observed for reemerging symptoms of mania.

LITHIUM

Prelithium Workup

CASE 87-2

QUESTION 1: C.N., a 21-year-old woman, was diagnosed with her first episode of mania 3 weeks ago. At that time, she was hospitalized and treated with olanzapine 15 mg daily. C.N.'s was stabilized, and after 10 days, she was discharged from the hospital. She was scheduled to see an outpatient psychiatrist for follow-up 1 week later, but she failed to keep the appointment. Today, C.N. arrives at the emergency department at the request of her mother. C.N. is grabbing her mother's hair and kicking wildly as she is pulled from the car. She can be heard screaming "The FBI is after me, Mom! You want them to find me, don't you? I would have made it out of the country if you hadn't gotten in the way! I was going to marry Prince Charles and become the new queen of England." On evaluation, C.N.'s mood is irritable, and she is pacing around the interviewer. She is dressed in a short skirt and high heels and is wearing an excessive amount of makeup and costume jewelry. During the interview, she interrupts the examiner, smiles, and says in a loud, provocative voice, "Let's you and me get out of here!" Her mother states that after C.N. was discharged from the hospital, she stopped taking her olanzapine due to gaining some weight and, within several days, stopped attending her classes at the local community college. She began staying out late, playing her radio loudly, and driving recklessly, finally hitting the side of the garage while parking early this morning. The clinician would like to admit C.N. to the inpatient unit and initiate lithium treatment. What laboratory tests are required before initiating lithium therapy for C.N.?

Because lithium can affect many organ systems, baseline laboratory values must be evaluated before therapy is initiated. Baseline laboratory tests are useful in determining contraindications to the use of lithium or conditions that may require an adjustment in dosage. As a young, healthy female, C.N.'s prescreening laboratory battery should include electrolytes, blood urea nitrogen, creatinine, urine specific gravity, thyroid-stimulating hormone (TSH), thyroxine (T_4), and a CBC (Table 87-3). Also, a pregnancy test should be obtained before starting therapy since lithium is a known teratogen.

Table 87-3

Routine Monitoring During Lithium Therapy

	Baseline	Every 1–3 Months	Yearly
CBC	X		
Electrolytes	X		X
Renal function[a]	X		X

ECG[b]	X		X
Urine	X		
Thyroid function	X		X
Lithium level[c]		X	
Weight or BMI	X		X
Pregnancy[d]	X		

[a] Monitor more often in patients with history of kidney disease.

[b] Patients ≥45 years or those with history of cardiac disease.

[c] Weekly monitoring during the first month of treatment is often recommended.

[d] Women of childbearing potential.

BMI, body mass index; CBC, complete blood count; ECG, electrocardiogram.

Dosing

CASE 87-2, QUESTION 2: C.N.'s baseline laboratory parameters were normal, and her pregnancy test was negative. How should lithium treatment for C.N. be initiated?

Although there are many strategies for calculating lithium dosage requirements, it is simplest to begin C.N. at a dosage of 300 mg twice daily. This is a common starting dose for a healthy adult patient.

Patients experiencing an acute manic episode require higher lithium levels compared with maintenance therapy. The goal for the acute management of C.N. is a serum level between 0.8 and 1.2 mEq/L.[11] Because lithium is not immediately effective, C.N.'s lithium dosage can be adjusted based on the results of lithium serum levels checked weekly until the manic episode resolves. As she recovers and enters the maintenance phase of treatment, both C.N.'s lithium dosage and her lithium levels will require re-evaluation (see Case 87-8, Question 1).

CASE 87-2, QUESTION 3: How long will it take for C.N. to get the full effect of lithium?

The half-life of lithium in a young patient with normal renal function is approximately 24 hours; therefore, steady-state concentrations are typically achieved in approximately 5 days. The onset of action is slow, taking as long as 1 to 2 weeks to fully exert its therapeutic effects.[11] Because of the delay in onset, it is appropriate to use an adjunctive medication to help reduce C.N.'s acute symptoms. Both benzodiazepines and antipsychotics have been used in this manner.[11] AAPs are preferred over typical antipsychotics (see also Chapter 85, Schizophrenia) and have been demonstrated to enhance efficacy and accelerate time to response when used in combination with lithium in acute mania.[48] Benzodiazepines work rapidly to reduce agitation, anxiety, and decreased need for sleep.[100]

Adverse Effects

CASE 87-2, QUESTION 4: After 3 weeks of lithium therapy, C.N. is demonstrating significant improvement in her sleep, impulsivity, delusions, and activity level. She has achieved a lithium carbonate dose of 1,200 mg/day, and her lithium level is 0.8 mEq/L. Today she is complaining to the clinical staff that she has developed a hand tremor. Soon after her clinician arrives to evaluate her, C.N. asks to be excused so that she can go to the bathroom. How might C.N.'s presentation be related to her medication?

When considering adverse effect management early in lithium therapy, it becomes important to monitor lithium levels closely. When patients start to recover from acute mania, the rate of lithium clearance may decrease and patients may demonstrate an increase in lithium levels and worsening side effects (Table 87-4). This does not seem to be the case with C.N. because her lithium level is within the accepted range for the management of acute mania.

C.N. is complaining of a hand tremor. She should be interviewed and examined to determine its origin. Lithium-induced tremor occurs in 10% to 65% of treated patients and is characteristically rapid, regular, and fine in amplitude.[100,101] Often, this tremor occurs early in therapy and improves with time. Caffeine, personal or family history of tremor, alcoholism, anxiety, antidepressants, antipsychotics, and possibly older age enhance the risk of lithium-induced tremor.[101] The tremor is more common in patients with higher serum concentrations and may be worse at times of peak lithium levels.[11] If C.N. is not bothered by the tremor and suffers no impairment, treatment is not necessary. If the tremor becomes problematic, her lithium dosage may be reduced or a β-adrenergic blocking agent can be added. Propranolol is the most commonly used. Additionally, switching to a sustained-release lithium preparation may reduce peak serum levels and ameliorate tremors if associated with peak concentrations.[11] Because it is early in treatment and C.N. has only a moderate lithium level, it is reasonable to add propranolol 10 mg 3 times a day rather than to reduce the lithium dosage (if an intervention is required). Propranolol usually is effective at dosages less than 160 mg/day.[101] C.N. should be educated about her tremor, the adverse effects of propranolol (see Chapter 9, Essential Hypertension) and instructed to minimize her caffeine consumption.

Table 87-4

Lithium Adverse Effects

Adverse Effect	Considerations
ECG changes	T-wave suppression, delayed or irregular rhythm, increase in PVCs; SSNS; myocarditis
Edema	Primarily ankles and feet; transient or intermittent; secondary to effects on sodium and carbohydrate metabolism; caution about diuretics and sodium restriction to avoid lithium toxicity

Acne	Worsens
Psoriasis	Treatment-refractory worsening
Rashes	Maculopapular and follicular
Hypothyroidism	About 5% goiter; about 30% clinically significant hypothyroidism; may diminish sex drive
Hyperparathyroidism	Clinically not significant
Teratogenicity	Ebstein anomaly (tricuspid valve malformation, atrial septal defect); educate female patients, encourage advanced planning regarding pregnancy.
Anorexia, nausea (10%–30%)	Usually early in treatment and usually transient; may be early sign of toxicity
Diarrhea (5%–20%)	Slow-release preparations may help
Leukocytosis	May be useful in disorders such as Felty syndrome, iatrogenic neutropenia
Tremor (10%–65%)	Dose-related; men > women; worse with antidepressants and antipsychotics; reduce dose or use β-blocker
Cognitive disruption (10%)	Worsens compliance; perceived as "mental dulling"
Fatigue or weakness	May be early toxicity; may mimic depression
Polyuria-polydipsia (nephrogenic diabetes insipidus)	May be an indication of morphological changes; requires adequate hydration

CBZ, carbamazepine; ECG, electrocardiogram; PVC, premature ventricular contraction; SSNS, sick sinus node syndrome.

In addition, C.N. should be asked about her trip to the bathroom during this clinic visit because lithium may cause both diarrhea and polyuria. Polyuria and polydipsia are common, occurring in up to 60% of patients.[102] Nephrogenic diabetes insipidus is less common, affecting about 10% of patients on long-term treatment.[103] Nephrogenic diabetes insipidus (see Chapter 53, Diabetes Mellitus) is dose dependent, so C.N. can be told that a lower lithium dose may minimize the symptoms. Although the advantages of once-daily administration of lithium are not universally accepted, switching a stabilized patient to this schedule with its lower trough levels may help to reduce urine volume.[11] If C.N. were to fail to respond to either of these interventions, amiloride could be administered, which minimizes lithium's effect on free water clearance.[11,104]

If C.N.'s trip to the bathroom was because of diarrhea, lithium should be evaluated as a possible cause; up to 20% of patients started on lithium experience diarrhea, epigastric bloating, and sometimes stomach pain early in therapy.[105] Diarrhea from lithium is associated with high serum levels, once-daily dosing, and rapidly absorbed preparations; therefore, divided doses may help to alleviate the problem. Use of lower doses and switching to sustained-release preparations are alternative strategies that could be used if C.N. is experiencing diarrhea or polyuria. Her fluid status and lithium level also should be monitored closely. Dehydration leads to increased lithium reabsorption in the proximal tubule and could result in accumulation and lithium toxicity.

CASE 87-2, QUESTION 5: What should C.N. be told regarding potential renal damage from lithium?

C.N. should be informed that lithium could adversely affect her kidneys. Long-term treatment has been associated with reduced kidney function and, rarely, end-stage renal disease.[106] Routine monitoring of renal function (Table 87-3) allows for the identification of patients with precipitous declines in glomerular filtration. In such patients, lithium should be discontinued to prevent progression to end-stage renal disease. Risk factors for renal insufficiency include episodes of lithium intoxication, medical conditions that impair glomerular filtration (e.g., hypertension, diabetes mellitus), and concurrent medications that are damaging to the kidney.[107] Communication with her physician about situations that increase the risk of lithium toxicity (see Case 87-2, Question 7) and cooperation with regular lithium and renal function monitoring can vastly reduce the risk of renal disease. Finally, C.N. must be informed that polyuria is not related to any of the more serious renal side effects.

Patient Education

CASE 87-2, QUESTION 6: What lithium education should C.N. receive prior to discharge from the hospital?

As with all medications, C.N. should be instructed to disclose all medications she is taking to each of her healthcare providers. She should be informed that dehydration, fever, vomiting, or sodium-restricted diets could lead to increases in her lithium level. Therefore, she needs to drink plenty of fluids and should avoid restricting sodium.

C.N. should be instructed to contact her physician if she starts to experience any symptoms of lithium toxicity, including worsening tremor, slurred speech, muscle weakness or twitches, or difficulty walking. C.N. should be told to use caution in selecting over-the-counter medications. Specifically, she should be warned to avoid the use of preparations containing nonsteroidal anti-inflammatory drugs, which can increase lithium levels.[108] C.N. should know that caffeine can sometimes be troublesome in patients taking lithium, worsening tremor on a short-term basis and lowering lithium levels during the long term.[108] With regard to serum lithium level monitoring, C.N. needs to know that lithium levels usually are drawn approximately 12 hours after a dose of lithium. If she is taking lithium in the evening and the morning, she should take her evening dose and then report for a blood sample to be drawn in the morning before taking her morning dose.

Toxicity

CASE 87-2, QUESTION 7: About 6 months after discharge, C.N.'s mother calls, concerned that C.N. has been complaining of nausea, vomiting, and diarrhea for several days. During the past few hours, C.N. has become confused and has developed a coarse tremor and slurred speech. It has been 4 months since C.N.'s lithium level has been checked. The only change is that C.N. recently started taking naproxen for headaches. What action should be taken?

There is a strong possibility that C.N. is suffering from lithium toxicity, which can occur acutely from an overdose or insidiously from reduced lithium clearance. Mild toxicity at levels less than 1.5 mEq/L causes feelings of apathy, lethargy, and muscle weakness accompanied by nausea and irritability. Moderate toxicity occurs between 1.5 and 2.5 mEq/L with symptoms progressing to coarse tremor, slurred speech, unsteady gait, drowsiness, confusion, muscle twitches, and blurred vision. Severe toxicity at levels greater than 2.5 mEq/L can result in seizures, stupor, coma, renal failure, and cardiovascular collapse. C.N. seems to be experiencing moderate lithium toxicity. She should stop any medications that can decrease lithium clearance and the lithium itself until instructed to resume it. She should be taken to the emergency department immediately, where stat laboratory tests, including a lithium level, electrolytes, and renal function tests, should be ordered. There is no antidote for lithium intoxication. Intravenous solutions should be started to ensure that C.N. is hydrated adequately, and electrolyte abnormalities should be corrected promptly. Depending on the results of physical examination and laboratory tests, cardiac monitoring should be instituted and hemodialysis should be considered. Hemodialysis is used to shorten the exposure of different tissues of the body to the elevated lithium concentration and to lower the lithium level to 1.0 mEq/L. Mohandas and Ramjmohan suggest that candidates for hemodialysis include those with: compromised renal function, severe (irreversible) neurological symptoms, acute lithium ingestions where symptoms are clear and serum levels are greater than 4.0 mEq/L, or a chronic toxicity where lithium levels exceed the therapeutic values with a clearly manifested clinical picture.[109]

Hypothyroidism

CASE 87-2, QUESTION 8: After receiving lithium 1,200 mg/day for 1 year, C.N. returns complaining that the lithium is slowing her down. She is tired and has gained weight in recent weeks and thinks that she is becoming depressed. In the examining room, C.N. complains that the temperature is too cold. What is the most likely cause of C.N.'s complaints? What treatment should be instituted?

C.N.'s symptoms are consistent with those of hypothyroidism.

Lithium affects the incorporation of iodine into thyroid hormone, interferes with secretion of thyroid hormones, and may interfere with the peripheral conversion of T_4 to T_3 (triiodothyronine).[110] According to laboratory indices, the incidence of hypothyroidism in lithium-treated patients with BD ranges from 28% to 32%

compared with 6% to 11% in patients not taking lithium.[111] Risk factors for lithium-induced hypothyroidism include female gender, family history of hypothyroidism or thyroid illness in first-degree relatives, weight gain, elevated baseline TSH, preexisting autoantibodies, an iodine-deficient diet, rapid cycling, and elevated lithium levels.[112] For women, the first 2 years of treatment is a period of heightened risk as well as for any middle-aged patient starting lithium.[112]

Thyroid function tests should be ordered to evaluate C.N.'s current symptoms. If she is found to be hypothyroid, discontinuation of lithium is not necessary. She should receive levothyroxine in doses that normalize her thyroid function tests. Even if she has an elevated TSH with normal levels of T_3 and T_4, low-dose thyroid supplementation may help to resolve her symptoms, and prevent breakthrough depression.[110]

Drug and Dietary Interactions

CASE 87-3

QUESTION 1: T.J., a 35-year-old man, is hospitalized and treated with lithium for a severe manic episode. He had a stable lithium level of 0.84 mEq/L for several weeks, but his last two levels were 0.65 and 0.61 mEq/L without any change in his drug therapy. T.J. insists that he is taking the medication as prescribed. The nursing staff believes that he is adherent with his medication but notes that he is spending more time off the unit and in the cafeteria. What factors could contribute to a decrease in T.J.'s lithium levels?

Drug interactions are a common cause of changes in lithium levels, but there have been no changes in T.J.'s regimen (Table 87-5 provides a list of clinically significant drug interactions). Changes in formulation or brand may sometimes have an impact on lithium levels. Nevertheless, lithium is relatively well absorbed and has a long elimination half-life, so this usually does not result in large changes in the 12-hour postdose lithium level. Occasionally, patients switched from lithium citrate to solid dosage forms experience small changes in lithium levels.

T.J. should be questioned about his visits to the cafeteria because diet can have a major influence on lithium excretion. If T.J. is consuming large amounts of caffeinated beverages or salty snacks, a reduction in lithium levels could occur. Increases in dietary sodium intake and the ingestion of methylxanthines (e.g., caffeine, theophylline) can increase lithium clearance.[108]

Finally, acute mania can increase lithium clearance.[7] If T.J. was showing signs of a relapse, his decrease in lithium levels might be attributable to his return to a manic state.

Lithium in Pregnancy

CASE 87-4

QUESTION 1: A.J., a 36-year-old woman, has been maintained successfully on lithium therapy for 5 years for BD. She asks whether she should stay on lithium because she plans to become pregnant in the near future.

While there is considerable disagreement about the importance of lithium as a teratogen, it has been associated with a variety of congenital malformations, including the rare cardiac malformation, Ebstein anomaly.[113] Lithium was originally thought to increase the risk of Ebstein anomaly 400 times; however, the risk is more likely 20 to 40 times higher than in the general population.[114] The current estimated overall risk for congenital malformations related to lithium treatment is approximately 4% to 12% (compared with 2%–4% in controls).[115] Because malformations are most likely to occur in the first trimester of pregnancy, it is advisable for patients to avoid lithium, when possible, during this high-risk period.

Table 87-5

Lithium Drug Interactions of Clinical Significance

Drugs That Increase Lithium Levels	
NSAIDs	Many NSAIDs have been reported to increase lithium levels as much as 50%–60%. This probably is owing to an enhanced reabsorption of sodium and lithium secondary to inhibition of prostaglandin synthesis.
Diuretics	All diuretics can contribute to sodium depletion. Sodium depletion can result in an increased proximal tubular reabsorption of sodium and lithium. Thiazide-like diuretics cause the greatest increase in lithium levels, whereas loop diuretics and potassium-sparing diuretics seem to be somewhat safer.
Angiotensin-Converting Enzyme (ACE) inhibitors	ACE inhibitors and lithium both result in volume depletion and a reduction in glomerular filtration rate. This results in reduced lithium excretion.
Angiotensin II Receptor Blockers (ARBs)	ARBs decrease in sodium and reabsorption via AT_1 blockade results in reduced lithium excretion.
Drugs That Decrease Lithium Levels	
Theophylline, caffeine	Theophylline and caffeine may increase renal clearance of lithium and result in a decrease in levels in the range of 20%.
Acetazolamide	Acetazolamide may impair proximal tubular reabsorption of lithium ions.
Sodium	High dietary sodium intake promotes the renal clearance of lithium.
Drugs That Increase Lithium Toxicity	
Methyldopa	Cases of sedation, dysphoria, and confusion owing to the combined use of lithium and methyldopa have been reported.
Carbamazepine	Cases of neurotoxicity involving the combined use of lithium and carbamazepine have been reported in patients with normal lithium levels.
Calcium-channel antagonists	Cases of neurotoxicity involving the combined use of lithium and the calcium-channel blockers verapamil and diltiazem have been reported. Lithium interferes with calcium transport across cells.
Antipsychotics	Cases of neurotoxicity (encephalopathic syndrome, extrapyramidal effects, cerebellar effect, EEG abnormalities) have been reported owing to the combined use of lithium and various antipsychotics. The interaction may be related to increase in phenothiazine levels, changes in tissue uptake of lithium, or

dopamine-blocking effects of lithium. Studies attempting to demonstrate this effect have yielded differing results.
Serotonin-selective reuptake inhibitors
Fluvoxamine and fluoxetine have been reported to result in toxicity when added to lithium. Sertraline has been reported to cause nausea and tremor in lithium recipients.

ACE, angiotensin-converting enzyme; EEG, electroencephalogram; NSAIDs, nonsteroidal anti-inflammatory drugs.

In addition to cardiac malformations, infants exposed to lithium have been reported to have hypotonia, nephrogenic diabetes insipidus, and thyroid abnormalities.[113] Lithium administration during pregnancy increases the risk of premature delivery by a factor of two to three.[116] Unfortunately, the relative safety of other

---

psychotropic agents commonly used in BD is either not ideal or unknown. VPA and CBZ are categorized as US Food and Drug Administration (FDA) category D during pregnancy; the general consensus is that these medications are genuine teratogens and should be avoided.[117] Among 1,558 exposures, lamotrigine, FDA category C, had 35 major congenital malformations among first trimester monotherapy exposures (2.2%, 95% CI = 1.6%–3.1%).[118]

Typical and most atypical antipsychotics are classified as pregnancy category C, suggesting that adverse morphologic outcomes are less common with these treatments than with mood stabilizers. Clozapine and lurasidone are pregnancy category B. In a comparison of AAPs of placental passage, olanzapine was associated with the highest exposure (72% ratio of umbilical cord-to-maternal plasma concentrations), followed by haloperidol (65%), risperidone (49%), and quetiapine (24%).[119] Olanzapine was also associated with the highest rates of low birth weight and neonatal intensive care unit admissions.

A.J. and her physician should discuss her individual risks related to lithium treatment. In addition to the risks of teratogenicity, they must consider the harm that could result from the possible recurrence of episodes of mania or depression and the risks inherent in discontinuing lithium or switching to another antimanic agent. Also, A.J. should be actively involved in the decision-making process.

If A.J. and her physician decide that she is to remain on lithium, her serum levels must be monitored closely during pregnancy and her dosage adjusted accordingly. Lithium clearance increases during the third trimester by 30% to 50%, resulting in a reduction in lithium levels and a need for dosage adjustment.[114] Approximately 16 to 18 weeks after conception, screening tests, high-resolution ultrasound, and fetal echocardiography can be used to determine whether cardiac defects have developed.[114] If possible, A.J.'s physician should consider decreasing the lithium dose before delivery to minimize lithium levels in the newborn and to offset the reduction in lithium excretion that occurs after delivery.[114]

If A.J. and her physician decide that she is to discontinue lithium, they must be prepared to deal with the risks of lithium discontinuation. Several cases of presumed rebound mania have occurred after abrupt cessation of lithium therapy. If lithium is to be discontinued in A.J., it should be gradually reduced over at least 4 weeks.

CASE 87-4, QUESTION 2: A.J. did not use lithium throughout her pregnancy. After delivery, A.J. and her physician decide to restart lithium. How soon can lithium be reinitiated in A.J.?

Lithium can be restarted as soon as A.J.'s urine output is established and she is fully hydrated. However, this decision also may be affected by whether or not A.J. chooses to breastfeed her child because lithium passes into breast milk and is present in concentrations up to 72% of that found in the maternal blood.[114] Risks to the newborn include hypothyroidism, cyanosis, hypotonia, lethargy, and cardiac dysrhythmias. Hydration status must be closely monitored because lithium toxicity may develop during infantile illnesses. Thus, A.J. and her physician must discuss the advantages of breastfeeding versus the risks of exposing the newborn to lithium or withholding lithium during the postpartum period. A.J. should be informed that approximately 40% to 70% of women with BD experience affective episodes after delivery.[114–119]

If A.J. chooses to breastfeed while taking lithium, she should consider using infant formula when the child becomes ill because febrile illness, vomiting, and diarrhea can increase the risk of lithium toxicity. She also should be instructed to contact her pediatrician if the infant experiences diarrhea, vomiting, hypotonia, poor sucking, muscle twitches, restlessness, or other unexplained changes in behavior.

Atypical Antipsychotics

CASE 87-5

QUESTION 1: D.W., a 34-year-old female singer and musician, recently experienced her fourth hospital admission for a manic episode. Her past medical history includes psoriasis and asthma. A trial of lithium led to worsening of her psoriasis and an unacceptable tremor, which interfered with her guitar playing. Use of propranolol was not considered because of her asthma. She was subsequently switched to VPA monotherapy; however, tremor has again become problematic. Furthermore, she is concerned about her appearance because she has begun to experience weight gain and hair loss from the VPA. What other drugs are available for the treatment of acute mania?

AAPs can be selected as first-line choices for the treatment of acute mania.

Three recent systematic reviews and meta-analyses support the efficacy of AAPs as a class.[120–122] Perlis et al.[120] reviewed data from 12 randomized, placebo-controlled, monotherapy studies and six adjunctive studies and found a collective response rate of 53% for AAPs compared with 30% for placebo. There was no difference in response between the individual AAPs. In adjunctive studies, the mean odds ratio was 2.4 for a 50% improvement with the addition of an AAP to a mood stabilizer (primarily lithium or VPA). Scherk et al.[121] conducted a meta-analysis of

24 randomized controlled trials and found superiority of AAPs for acute mania in comparison with placebo and equal efficacy to lithium, VPA, and haloperidol. In this analysis, the addition of an AAP to lithium, VPA, or CBZ was found to be more effective in reducing manic symptoms and yield less treatment discontinuation than lithium or the anticonvulsant alone. The results of a different meta-analysis specifically designed to evaluate combination treatment of AAPs with lithium or an anticonvulsant also found greater efficacy for the combined regimen.[122] In most combination therapy studies, AAPs were limited to patients having no response or only a partial response to lithium or an anticonvulsant. Thus, the utility of drug combinations as initial therapy cannot be directly assessed.

In a more recent systematic review of 68 randomized controlled trials [eliminate "to"] comparing the efficacy and acceptability of antimanic drugs either against placebo or against one another in the treatment of acute mania was completed via a multiple-treatment meta-analysis. Fourteen treatment options were analyzed including: aripiprazole, asenapine, carbamazepine, valproic acid, gabapentin, haloperidol, lamotrigine, lithium, olanzapine, paliperidone, quetiapine, risperidone, topiramate, ziprasidone, and placebo. All of the antipsychotic drugs were found to be significantly more effective than mood stabilizers in the treatment of acute mania, with risperidone and olanzapine being ranked as superior for efficacy and tolerability. Lamotrigine, topiramate, and gabapentin were not significantly better than placebo in terms of efficacy and should not have a place in the treatment of acute mania.[123]

Additionally, a comparative analysis of 32 placebo-controlled trials demonstrated that YMRS scores improved significantly more with second-generation antipyschotics than mood stabilizers but the efficacy needs to be balanced against anticipated common adverse effects.[124] A significant concern about the use of AAPs is the risk of metabolic complications, including weight gain, glucose dysregulation, and dyslipidemia (see also Chapter 85, Schizophrenia). Clozapine and olanzapine have the highest risk for metabolic complications, quetiapine, iloperidone, paliperidone, and risperidone are associated with an intermediate risk, and ziprasidone, brexpiprazole, cariprazine, asenapine, lurasidone, and aripiprazole appear to have the lowest risk.[48,125] Clozapine is also associated with significant safety concerns, including agranulocytosis, seizures,

---

sialorrhea, anticholinergic side effects, and orthostasis. Efficacy data with clozapine are limited compared with the other AAPs, but clozapine appears to be effective in treatment-resistant mania and in long-term mood stabilization.[126–128]

Sedation is common with clozapine, olanzapine, asenapine, and quetiapine, and this effect may be beneficial in the treatment of acute mania; however, sedation can also lead to non-adherence with long-term use.[129] Aripiprazole and ziprasidone are less sedating; thus, the adjunctive use of a benzodiazepine is often necessary in the acute management of mania with these AAPs. Adjunctive benzodiazepines may also benefit treatment of emergent akathisia, which occurs in 11% to 18% of patients treated with aripiprazole.[130,131] Cariprazine has also been associated with treatment emergent akathisia and extrapyramidal disorders (>10%).[132] Asenapine can cause dysgeusia or oral hypoesthesia, although a black-cherry formulation can help with the unpleasant taste.[133] Ziprasidone may cause activation; however, this effect is attenuated at doses of 120 mg/day or more.[134] Risperidone may overall be the best tolerated of the AAPs, but this drug carries a higher risk for serum prolactin elevation and extrapyramidal symptoms.[135]

D.W.'s concern about her weight gain makes aripiprazole, cariprazine, asenapine, or ziprasidone rational choices for her manic episode. In addition to symptom response, D.W. should be monitored for characteristic antipsychotic side effects, such as movement disorders, and metabolic complications. If D.W. fails to respond to the initially selected AAP, a switch to a different AAP may prove beneficial given the variability in individual response.[47] Table 87-6 provides dosing information for AAPs approved for the treatment of acute mania.

CASE 87-5, QUESTION 2: What alternative agents are available for acute mania if lithium, VPA, or an AAP fail?

Anticonvulsants

CBZ represents an alternative treatment for the management of acute mania when lithium, VPA, and AAPs fail.[11,46,47] In 2005, the FDA-approved extended-release CBZ for the treatment of acute manic and mixed episodes based on the results of two double-blind, randomized, placebo-controlled trials.[136] A meta-analysis of four randomized, controlled trials (n = 464 patients) found that maintenance treatment with carbamazepine has similar efficacy as, and fewer discontinuations due to adverse effects than, lithium.[137] Despite demonstrated efficacy, CBZ remains a less than popular choice in BD due to significant tolerability and drug–drug interaction risks. If elected for treatment, CBZ should be started at 100 to 200 mg twice daily. The dose should be increased by 200 mg every 3 to 4 days until adequate serum levels have been reached.[11] Although no correlation between CBZ serum levels and response in BD has been established, serum levels greater than 12 mcg/mL are associated with sedation and ataxia. The recommended target serum level for seizure prophylaxis is 4 to 12 mcg/mL.[11] Average daily doses for maintenance therapy range from 200 to 1,600 mg/day (see Chapter 60, Seizure Disorders).

Oxcarbazepine, a structural analog of CBZ, offers some advantages over CBZ, including improved tolerability and fewer drug interactions; however, there is a paucity of well-designed clinical trials in BD.[138] Cochrane reviews suggest that there are insufficient trials of adequate methodological quality to recommend use for either acute or maintenance treatment for bipolar disorder.[139,140]

Other anticonvulsants studied in mania include lamotrigine, gabapentin, topiramate, tiagabine, zonisamide, and levetiracetam. Initial open-label studies of lamotrigine in mania were promising, but two unpublished trials were negative.[141] Currently, experts doubt that lamotrigine has any significant effect in acute mania. Open trials and case reports suggested adjunctive treatment with gabapentin was effective in manic, hypomanic, and depressive states of BD.[142–144] A more recent controlled trial found no benefit of gabapentin.[145] In this double-blind, placebo-controlled trial, gabapentin was administered as an adjunctive treatment in patients with bipolar I disorder whose current episode was manic, hypomanic, or mixed. At 12 weeks, gabapentin failed to show any significant benefit compared with placebo. In fact, the placebo group did significantly better than the gabapentin-treated patients.

In four double-blind, placebo-controlled trials, topiramate did not separate from placebo and was less effective than lithium in the treatment of acute mania.[146,147] Tiagabine, levetiracetam, and zonisamide have been studied in BD but lack adequate safety or efficacy data to receive any formal evaluation.

Table 87-6

Atypical Antipsychotic Dosing in Acute Mania

Atypical Antipsychotic	Initial Dose	Titration	Effective Dose Range
Aripiprazole	15 mg/day	Not required	15–30 mg/day
Asenapine	10 mg twice daily	5 mg twice daily	5–10 mg twice daily
Cariprazine	1.5 mg/day	Increase to 3 mg on day 2, then increase as needed in 1.5 or 3 mg increments	3–6 mg/day
Olanzapine	10–15 mg/day	5 mg/day	5–20 mg/day
Quetiapine	50 mg twice daily	50 mg twice daily	200–400 mg twice daily
Quetiapine XR	300 mg/day	300 mg/day	400–800 mg/day
Risperidone	2–3 mg/day	1 mg/day	1–6 mg/day
Ziprasidone	40 mg twice daily	20–40 mg twice daily	40–80 mg twice daily

COMBINATION TREATMENT

Despite the array of treatments available for the management of acute mania, large numbers of patients fail to respond to monotherapy, and combination therapy is becoming a first-line treatment option.[148] Potentially useful combinations include lithium plus AAPs, VPA plus AAPs, and lithium plus VPA. [35,46] A combination to be avoided is CBZ and clozapine owing to the increased risk of hematologic adverse effects. Also combinations of CBZ with either olanzapine or with risperidone result in more side effects and decreased efficacy; therefore, these combinations are not recommended.[47]

BENZODIAZEPINES AND ANTIPSYCHOTICS FOR ACUTE AGITATION

CASE 87-6

QUESTION 1: M.B. is a 39-year-old man hospitalized for an acute manic episode, but is refusing all medications, reporting "I will be robbed of my superpowers." He is found pacing around the inpatient unit shouting orders for his release. When asked to return to his room by the clinical staff, he becomes agitated, picks up a chair, and begins swinging it wildly at anyone who approaches him. In the past, M.B. experienced a documented acute dystonic reaction to haloperidol. M.B. has a medical history of diabetes mellitus and hypertension. What is an appropriate pharmacologic intervention for M.B.?

Benzodiazepines and antipsychotics are useful in treating agitation, irritability, and hyperactivity associated with acute manic episodes. Oral formulations are preferred and are favored by patients in psychiatric emergencies.[149] Oral dose delivery can be facilitated with liquid concentrates and orally disintegrating tablets. Patients refusing oral medications may require intramuscular (IM) injections.[150] Traditionally, the combination of IM haloperidol and IM lorazepam has been used. Currently, ziprasidone, aripiprazole, and olanzapine are available in rapid-acting IM dosage forms. IM ziprasidone at doses of 10 and 20 mg is effective in psychotic agitation.[151,152] IM aripiprazole at doses of 9.75 or 15 mg and IM olanzapine 10 mg are effective for manic or mixed-state agitation.[153,154] Repeat doses of IM ziprasidone, aripiprazole, and olanzapine can be administered 2 to 4 hours after the first dose, if needed. The concurrent use of a benzodiazepine with an antipsychotic is generally safe and potentially more effective than either agent alone. In the case of IM olanzapine, concurrent benzodiazepines should not be used because the combination may cause excessive sedation and cardiorespiratory depression.[155,156]

Lorazepam is the preferred benzodiazepine for acute manic agitation. Advantages of lorazepam include availability as both an IM and oral formulation (tablet and concentrate), lack of active metabolites, and safety in hepatic and renal impairment. The Expert Consensus Guideline recommends dosing lorazepam at 1 to 3 mg orally or 0.5 to 3 mg IM, with repeat doses at least 60 minutes apart. The maximal dose should not exceed 10 to 12 mg in the first 24 hours.[157] The primary concern regarding the use of benzodiazepines for agitated mania is sedation. The risk of abuse and addiction is minimal with short-term inpatient use.

M.B. is uncooperative and an immediate danger to others, thus warranting IM therapy. Because of M.B.'s history of acute dystonia to haloperidol, an IM AAP (such as olanzapine, ziprasidone, or aripiprazole) should be used. The combination of ziprasidone 10 mg IM and lorazepam 2 mg IM is an appropriate intervention. IM administration of aripiprazole and lorazepam may also be used. As M.B. becomes calmer and more receptive to treatment, he can be transitioned to oral therapy.

TREATMENT OF ACUTE BIPOLAR DEPRESSION

CASE 87-7

QUESTION 1: H.C., a 31-year-old woman, was hospitalized for treatment of an acute manic episode 3 months ago. She was discharged on VPA 1,750 mg/day with a favorable response. Starting about 2 weeks ago, her parents become concerned because H.C. started spending most of the day in bed. When out of bed, H.C. sits on the couch without moving for hours. She only nibbles at the food her parents offer her. She has no other signs or symptoms of physical illness and has not taken any additional medications, alcohol, or drugs of abuse to her parents' knowledge. They report that H.C. was diagnosed with diabetes mellitus type 2 last year. Her serum glucose has been controlled by diet. On further questioning, H.C.'s parents report that she has been intermittently tearful and expressed remorse for her behavior when she was manic. They also recall her as saying "I am as low as I can go, and I just want to die." Hence, they suspect she is suicidal. H.C.'s parents report that she is taking VPA as prescribed and that the last time she experienced this level of depression, the addition of lithium to VPA did not seem to help. Her VPA level on discharge was 84 mcg/mL. What change in H.C.'s treatment should be instituted at this time?

Bipolar depression is both recurrent and chronic, accounting for three-quarters of the time spent ill in BD.[158] Depression is often difficult to treat and puts patients at significant risk for suicide, which occurs at a rate 15 times greater than that of the general population.[159]

In bipolar depression, complete remission of symptoms is the primary goal of treatment. The ideal regimen should target acute depressive symptoms, decrease suicide risk, and prevent future mood episodes (both manic and depressive). These goals should be achieved without precipitating mania (switching) or mood cycling. Because simply addressing the acute depressive symptoms is often shortsighted in an illness with recurrent depressive episodes, the ability to prevent future depressive episodes and the long-term tolerability are important considerations.[160]

A logical first step in the management of bipolar depression is to verify adherence and optimize the dose of the current mood stabilizer.[35] For H.C., she is already on a therapeutic level of VPA; thus, no change in dose is needed.

Lithium

Lithium remains a first-line treatment for bipolar depression.[47,48] The CANMAT guidelines recommend a level of 0.8 mEq/L or more for optimal response.[49] The benefit of lithium was demonstrated in seven of eight placebo-controlled crossover studies with a mean response rate of 76%.[161] Lithium may also be effective for preventing depressive episodes. A 6-year follow-up study of patients maintained on lithium found a reduction in the annual rate of depressive episodes by 46% and the time spent ill by 53%.[162] A meta-analysis of 1- or 2-year-long studies found a 22% relative risk reduction for a depressive relapse compared with placebo (risk ratio, 0.78; 95% CI = 0.60–1.01).[163] The difference from placebo was not statistically significant.[156] Beyond antidepressant effects in BD, lithium also has the vital benefit of reducing the risk of suicide, deliberate self-harm, and all-cause mortality.[164,165]

Lamotrigine

Lamotrigine is recommended as a first-line treatment for bipolar depression by both the World Federation of Societies of Biological Psychiatry (WFSBP) and CANMAT guidelines; however, more recent data from five double-blind, placebo-controlled trials have brought this recommendation into question.[47,49] These studies did not detect any benefit from lamotrigine on the primary end points (change in Hamilton Depression Rating Scale [HAM-D], or Montgomery–Åsberg Depression Rating Scale [MADRS]) relative to placebo. An independent meta-analysis of the same five studies found significant (but only modest) benefits for lamotrigine with a relative risk of response of 1.27 for the HAM-D and 1.22 for the MADRS.[166] The ability of lamotrigine to reduce the risk of relapse to depression is less controversial. A pooled analysis of two long-term studies (up to 18 months) with lamotrigine found a 36% reduction in the risk of relapse to depression.[167] Lamotrigine was well tolerated with no difference from placebo in any side effect. Because lamotrigine has limited antimanic properties, patients with a history of severe, recent, or recurrent mania should only take lamotrigine in combination with an antimanic drug, such as lithium.[46]

The combination of lamotrigine and lithium may confer additional benefits on reducing depressive symptoms and should be considered for bipolar depression. Patients stabilized on lithium (predefined range of 0.6–1.2 mEq/L, mostly >3 months' duration) were randomly assigned to receive lamotrigine (200 mg/day) or placebo. The lithium–lamotrigine group had a response rate of 52% (based on MADRS scores) compared with 32% for the lithium–placebo group.[168] From the results of this study, clinical experience, and the need for long-term tolerability, the combination of lamotrigine and lithium is an appropriate treatment when monotherapy with these drugs has failed.

Due to valproate's inhibition of UGT2B7, it can increase lamotrigine's AUC by

2.6-fold. Clinicians should pay particular attention to the dosing with initiating or discontinuing either medication in the presence of the other medication.[91]

Atypical Antipsychotics

AAPs offer another option for the treatment of bipolar depression. Quetiapine has demonstrated efficacy in a total of four 8-week double-blind, placebo-controlled studies (300 or 600 mg/day).[169–172] Response rates ranged from 58% to 69% for the 300-mg dose, and 58% to 70% for the 600-mg dose. Both doses were commonly associated with sedation, somnolence, dry mouth, and dizziness. Clinically significant weight gain (≥7% of baseline weight) was detected in roughly 5% to 10% of subjects receiving quetiapine.

The combination of olanzapine with fluoxetine is effective for patients with bipolar depression.[173] In a 7-week acute-phase treatment, OFC was superior to lamotrigine in symptom improvement but not significantly different in response rate (69% with OFC vs. 60% with lamotrigine).[174] The rate of relapse to depression during the 6-month study was low and similar between OFC and lamotrigine (14% vs. 18%). In an extension of this study (for a total of 6 months), OFC caused significant elevations in all metabolic parameters (weight, glucose, prolactin, cholesterol).[175] Most alarming was a 34% incidence of clinically significant weight gain in the OFC group (vs. 2% with lamotrigine). Therefore, the risk of metabolic complications should be taken into consideration when selecting this treatment.

Lurasidone has demonstrated efficacy in two 6-week, randomized, double-blind controlled clinical trials as monotherapy at either 20 to 60 mg/day and 80 to 120 mg/day. Response rates were 53% for the low dose, 51% for the high dose, and 30% for placebo. An additional study with a similar design failed to separate from placebo. An adjunct to lithium or VPA trial demonstrated response rates of 57% of lurasidone with either lithium or VPA compared to 42% of placebo with either lithium or VPA.[176–178] Table 87-7 provides dosing information for AAPs approved for the treatment of bipolar depression.

Despite its efficacy in treatment-resistant unipolar depression, aripiprazole does not appear to be effective for bipolar depression on the basis of two randomized, controlled trials.[172,179] Considering these findings, the CANMAT guidelines have listed aripiprazole as not recommended for acute bipolar depression.[49] Other AAPs have not been systematically studied in bipolar depression.

Antidepressants

The use of antidepressants in BD has been hotly debated. Some guidelines recommend restrictive use of antidepressants because of concerns about mood switching and cycle acceleration.[48] Other guidelines recommend early treatment with antidepressants, particularly SSRIs, to address the recurrent depressive episodes.[47] In either case, there is agreement that antidepressants should only be used in combination with antimanic agents such as VPA, lithium, or an AAP. [47,48] The largest controlled trial of antidepressant augmentation in bipolar depression was conducted as part of the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) study. This study was a naturalistic 26-week, double-blind, placebo-controlled trial comparing antidepressants (bupropion or paroxetine) with placebo as adjunctive treatment to an antimanic agent.[81] The primary end point of durable recovery (euthymia for 8 weeks) was achieved in 24% of antidepressant-treated subjects compared with 27% receiving placebo. There was no significant difference between groups in treatment emergent mood switch. A recent meta-analysis of 15 studies, primarily with bupropion or SSRIs, found that antidepressants were no more effective than placebo for acute (<16 weeks) bipolar depression.[180] This study also did not find an increased risk of mood switch. Therefore, although it appeared to be safe to add the antidepressant in regard to switching into mania, there is question about whether there is a large benefit on depressive symptoms.

Table 87-7

Atypical Antipsychotic Dosing in Bipolar Depression

Atypical Antipsychotic	Initial Dose	Titration	Effective Dose Range
Lurasidone	20 mg/day	20 mg every 2 days	20–120 mg/day
Olanzapine/Fluoxetine	6/25 mg/day	As indicated	12/50 mg/day
Quetiapine (IR and XR)	50 mg/day	100 mg Day 2 200 mg Day 3 300 mg Day 4	300 mg/day

Source: Latuda (lurasidone) [package insert]. Marlborough, MA: Sunovion Pharmaceuticals; July 2013; Symbyax (olanzapine/fluoxetine) [package insert]. Indianapolis, IN: Lilly USA, LLC.; January 2015; Seroquel XR (quetiapine XR) [package insert]. Wilmington, DE: AstraZeneca; July 2009.

Because H.C. did not respond to lithium in combination with VPA during her past depressive episode, an alternative first-line agent such as lamotrigine is a reasonable choice. OFC or quetiapine may compromise her type 2 diabetes control and thus are not appropriate options. Lurasidone would also be an alternate choice, although no current data exist in comparing it to lamotrigine, quetiapine, or OFC for the treatment in bipolar depression. Dosing of lamotrigine needs to account for H.C.'s concurrent use of VPA, which is known to inhibit the metabolism of lamotrigine. Therefore, the initial dose for H.C. is 25 mg every other day for weeks 1 and 2 followed by an increase to 25 mg/day for weeks 3 and 4. The dose can be increased to 50 mg/day for week 5 and then to a maximum of 100 mg/day beginning at week 6. In the absence of

VPA, the recommended target dose of lamotrigine is 200 mg/day. In patients taking enzyme inducers (e.g., CBZ), the target dose is 200 mg twice daily.[181] The appropriate titration schedule must be followed for lamotrigine (see also Chapter 60, Seizure Disorders) because of the risk of skin rash, which may progress to the life-threatening Stevens–Johnson syndrome. The combination of lamotrigine and VPA is a risk factor for the development of this dangerous cutaneous reaction; therefore, H.C. should be instructed to contact her physician immediately if a skin rash develops.

MAINTENANCE THERAPY OF BIPOLAR DISORDER

CASE 87-8

QUESTION 1: R.L., a 33-year-old man, has been treated for an episode of acute mania with lithium 600 mg twice a day for 3 weeks. He is no longer overtly manic. Because of R.L.'s past episodes of depression and mania, his physician decides to institute prophylactic (maintenance) lithium therapy. What are the goals of maintenance lithium therapy for R.L.? How should he be monitored during this maintenance phase? How long should R.L. be maintained on lithium?

Recurrent episodes are associated with decreased quality of life, poorer response to treatment, longer hospitalizations, and cognitive impairment.[35] Thus, early maintenance (prophylactic) treatment is indicated to prevent disease progression. Appropriate goals for maintenance therapy include an increase in the interval between episodes, a decrease in the frequency of episodes, and a reduction in the duration and severity of mood episodes. In most cases, patients will have been started on an acute treatment for a manic or depressive episode. These agents should generally be continued because abrupt switches in medications may predict poorer treatment outcomes.[35]

Lithium

The aforementioned meta-analysis (Case 87-7, Question 1) of long-term lithium therapy for relapse prevention in BD included five randomized, placebo-controlled studies.[163] Although lithium did not effectively reduce the risk of relapse to depression, it did reduce the risk of relapse to any mood episode (risk ratio, 0.66) and to manic episodes specifically (risk ratio, 0.62). The average risk of relapse to any mood episode on lithium was 40% versus 60% for placebo. The average risk of relapse to a manic episode was 14% for lithium versus 24% for placebo.

In the case of R.L., he should be continued on lithium. The target levels for maintenance therapy with lithium should be in the range of 0.5 to 0.8 mEq/L.[11] Higher levels ranging from 0.8 to 1.0 mEq/L are associated with a reduced number of relapses (compared with levels between 0.4 and 0.6 mEq/L) but also have an elevated risk of side effects.[182]

In addition to determining an appropriate maintenance lithium level for R.L., it is important to consider whether once-daily administration of lithium can improve adherence or adverse effects. During periods of dosage readjustment, R.L. will require monitoring of his lithium serum level more frequently. Once stabilized, the monitoring frequency can be reduced to quarterly. See Table 87-3 for recommended lithium monitoring guidelines.

CASE 87-8, QUESTION 2: What other maintenance treatments for BD are available should R.L. fail to respond to lithium?

Anticonvulsants

VPA and lamotrigine are reasonable alternatives to lithium that have shown efficacy in BD maintenance therapy. In the first controlled trial of VPA for the maintenance treatment of BD, patients were randomly assigned to receive VPA, lithium, or placebo and followed for 52 weeks.[183] The three groups did not differ with regard to the primary outcome of time to any mood episode. However, a lower percentage of patients discontinued treatment for any reason in the VPA group (62%) than lithium (76%) or placebo (75%); patients on VPA remained in the study longer (198 days) than patients on lithium (152 days) but not placebo (165 days). The mean VPA serum concentration was 85 mcg/mL. Lamotrigine has been studied rigorously in the maintenance treatment of BD. A pooled analysis of two placebo-controlled studies found that lamotrigine and lithium more than doubled the time to intervention (e.g., addition of pharmacotherapy or ECT) for any mood episode compared with placebo (see Case 87-7, Question 1).[167] The time to intervention was 197 days for lamotrigine, 187 days for lithium, and 86 days for placebo. Lithium preferentially prevented manic relapses, whereas lamotrigine preferentially prevented depressive episodes.

Atypical Antipsychotics

AAPs have become increasingly popular alternatives and adjunctive treatments for maintenance therapy of BD. To date, aripiprazole, olanzapine, quetiapine (adjunctive), risperidone long-acting injection, and ziprasidone (adjunctive) have received FDA approval for the maintenance treatment of BD (Table 87-8). A meta-analysis evaluated 20 trials (n = 5364) in the efficacy of maintenance treatments for BD. No monotherapy options were associated with significantly reduced risk for both manic/mixed and depressive poles compared to each other, while the only combination, quetiapine plus lithium or VPA demonstrated significant reduction in risk versus the comparator of placebo in reduced risk for both poles.[184] The long-term risk of side effects, including metabolic complications and EPS, should be the primary consideration for selecting one AAP over another (see Case 87-5, Question 1).

CASE 87-8, QUESTION 3: What is the role of psychotherapy in BD?

Psychotherapy can have a profound effect on the prevention of acute illness, as well as a sustained effect on maintenance treatments. Excessive stress, for example, is often implicated in the onset of affective episodes, particularly early in the lifetime course of BD.[7] If individuals and their families can learn to avoid these triggers or to develop coping skills, the acute impact can be minimized and future episodes averted.

Therapy may also help the family to cope with the extreme emotions and disruption that are the hallmark of acute manic and depressive episodes. Violent outbursts, infidelity, financial debts, substance abuse, suicidal thinking, and loss of self-esteem may all be a byproduct of mood recurrence, and family members must come to terms with such calamities, as well as fears surrounding future episodes. Regular sleep–wake cycles seem vital to the maintenance of euthymic states; thus, improvements in sleep hygiene may be encouraged in these sessions. Last, sustained medication adherence must also be emphasized; individuals with BD will often stop their medications in an effort to resume the “highs” of mania or because of the cumulative side effect burden of complex psychotropic regimens.

Table 87-8

FDA-Approved Medications for Bipolar Disorder

Drug	Mania	Mixed	Depression	Maintenance
Carbamazepine (extended-release capsule)	X	X		
Lamotrigine				X
Lithium	X			X
Valproate (divalproex sodium)	X	X		
Asenapine	X	X		
Aripiprazole	X	X		X
Lurasidone			X[a]	
Olanzapine	X	X		X
Olanzapine–fluoxetine			X	
Quetiapine	X		X	X[a]
Quetiapine XR	X	X	X	X[a]
Risperidone long-acting injection				X

Risperidone	X	X		
Ziprasidone	X	X		X[a]

[a] Monotherapy or adjunct to lithium or valproate.

FDA, Food and Drug Administration.

The specific psychotherapeutic approach to BD is generally quite similar to interventions offered to individuals with schizophrenia. Family-focused therapy seems to be quite effective, as are cognitive-behavioral and interpersonal and social rhythm therapy. Collaborative care models have been extensively studied for unipolar depression in primary-care settings, but the effectiveness of collaborative care models for bipolar illness is less clear. In fact, in the STEP-BD trials, collaborative care was the least effective intervention.[185] Reported response rates were 77% with family-focused therapy, 64% with interpersonal and social rhythm therapy, 60% with cognitive-behavioral therapy, and 54% with collaborative care. Experts contend that the collaborative care intervention was comparatively less intensive than the other three treatment modalities in this report.

Although most experts advocate for regular physical activity to prevent bipolar mood swings, the body of literature supporting such an approach is very limited. Lifestyle surveys have demonstrated that people afflicted with BD are less likely to exercise and more likely to exhibit poor dietary habits than those without a serious mental illness.[186] Theoretically, exercise may improve dietary habits, regulate sleep, increase energy, and promote euthymic moods. As a result, increased physical activity would be expected to improve the prognosis of bipolar illness and should be encouraged at the very least for the physical health benefits.

CASE 87-8, QUESTION 4: Are there other treatment options for BD?

Alternative Medicines

A wide variety of herbal preparations and dietary supplements have been studied for the treatment of BD. A meta-analysis of double-blind, placebo-controlled trials of combined bipolar and unipolar depression found significant benefit of omega-3 fatty acid supplementation compared with placebo in patients with depressive episodes.[187] In most cases, omega-3 fatty acid supplementation, including eicosapentaenoic acid alone or in combination with docosahexaenoic acid, was used as adjunctive treatment. The doses studied ranged from 1 g/day of eicosapentaenoic acid to 9.6 g/day of combined eicosapentaenoic acid and docosahexaenoic acid.

Inositol was recently compared with lamotrigine and risperidone in an augmentation trial for bipolar depression.[188] The three treatments were equivalent with regard to recovery from depression; however, the study was open label and the sample size was small (n = 66). Saint-John's-wort and S-adenosyl-L-methionine may be effective for depressive episodes; however, these agents, like traditional antidepressants, should generally be avoided in BD owing to the risk of mood destabilization.[55,56]

Electroconvulsive Therapy

ECT is effective in all phases of BD and continues to play a vital role in the contemporary treatment of mood disorders. The efficacy of ECT in bipolar depression is equivalent to unipolar depression with approximately 80% of patients achieving a response and 60% meeting criteria for remission.[189] The benefits of ECT in acute mania are similarly impressive. In a review spanning 50 years of research, "remission or marked clinical improvement" was achieved in 80% of patients.[190,191]

BD medication regimens need to be carefully evaluated before ECT treatment. Anticonvulsants and benzodiazepines raise the seizure threshold and interfere with the effectiveness of ECT. A retrospective analysis found that patients taking anticonvulsants achieved the same overall clinical response but required more ECT treatments and a longer hospital stay.[192] An exception is the concurrent use of lamotrigine, which appears to have no significant effect on electrical stimulus dose or seizure duration.[193] Lithium use with ECT has been discouraged on the basis of early reports of organic brain syndrome; however, a more recent prospective study found the combination to be safe in a younger population without risk factors for ECT complications.[194,195] Small case series and clinical experience suggest that AAPs are safe to use during ECT.[196–198]

ECT remains an effective and important tool for the treatment of BD, particularly bipolar depression, which is highly recurrent and has limited safe and effective treatment options. All patients failing to respond to standard BD pharmacotherapy, presenting with severe mood symptoms, or not otherwise appropriate for medication treatment should be considered for ECT.

Developmental Disorders

Lee A. Robinson and Kimberly Lenz

	CORE PRINCIPLES	CHAPTER CASES
1	Developmental disorders are a group of conditions in which early brain development is impaired. This very large group of disorders includes diagnoses such as intellectual disability (ID) and autism spectrum disorder (ASD). The core diagnostic features of ASD include impairment in reciprocal social communication and social interaction, and restricted, repetitive patterns of behavior, interests, or activities. These symptoms must be present from early childhood and impair everyday functioning. ASD is diagnosed clinically, though standardized behavioral diagnostic instruments can assist this process. ASD is more common in boys than girls, and the core diagnostic features can be addressed through multiple different types of nonpharmacologic interventions, including specialized education, physical therapy, occupational therapy, speech and language therapy, and behavioral therapy, such as applied behavior analysis (ABA).	**Case 88-1 (Question 1), Table 88-1**
2	Individuals with ID/ASD have high rates of comorbid ADHD. Treatment of ADHD, especially hyperactivity, in individuals with ID/ASD is similar to the treatment of ADHD in neurotypical individuals, and includes stimulants, α_2 agonists, and atomoxetine. Compared to their neurotypical peers though, individuals with ID/ASD and comorbid ADHD experience lower effect sizes with ADHD treatment, lower tolerated doses of ADHD medication, and more risk of adverse effects, including increased rates of decreased appetite, insomnia, depressive symptoms, irritability, and social withdrawal.	**Case 88-1 (Question 2)**
3	Some individuals with developmental disorders demonstrate symptoms of irritability and aggression, which can sometimes be helped with a pharmacologic intervention if nonpharmacologic interventions are ineffective. The strongest evidence for the pharmacologic treatment of irritability/aggression in individuals with developmental disorders exists for the use of risperidone and aripiprazole to treat irritability in children with ASD. Doses for this purpose are likely lower than those used to treat schizophrenia or bipolar disorder, and adverse events are relatively common and may include sedation, weight gain, and extrapyramidal symptoms.	**Case 88-2 (Question 1)**
4	Individuals with developmental disorders are at high risk of having comorbid anxiety and depression. Although no large prospective, randomized, controlled trials (RCTs) exist to support the use of selective	**Case 88-3 (Questions 1, 2)**

	serotonin reuptake inhibitors (SSRI) for this purpose, case studies and open-label studies have shown possible benefits. RCTs of SSRIs for the treatment of repetitive behavior in children with developmental disorders have shown mixed results, although they have demonstrated that individuals with developmental disorders may be at increased risk of emotional and behavioral adverse events from SSRIs, and therefore, target dosing should be lower than in individuals with typical development.	
5	Individuals with developmental disorders have high rates of comorbid medical and psychiatric disorders, and therefore may often be prescribed multiple different concurrent medications. Precaution should be taken to avoid any pharmacodynamic or pharmacokinetic drug–drug interactions, and such interactions should always be considered to describe any adverse events.	**Case 88-3 (Questions 1, 2)**
6	Sleep disturbances are common in individuals with developmental disorders. Melatonin has the strongest body of evidence for being a safe and effective treatment of sleep disturbances in this population.	**Case 88-4 (Question 1)**

Developmental disorders are a group of conditions characterized by impaired early brain development, resulting in deficits of cognitive, communicative, behavioral, sensory, or motor functioning. This broad group of disorders includes diagnoses such as intellectual disability, and autism spectrum disorder (ASD), which will be the focus of this chapter, attention-deficit/hyperactivity disorder (ADHD) and tic disorder, which are covered in another chapter, and communication disorders, learning disorders, cerebral palsy, congenital hearing loss, and congenital blindness. Intellectual disability (ID), previously labeled mental retardation, is a disorder with deficits in intellectual and adaptive functioning. Although ID is typically reserved for older children, for whom intellectual testing is more valid and reliable, global developmental delay (GDD) is the diagnosis given to younger children in which delays exist in two or more developmental domains. ASD, which includes prior diagnoses of autistic disorder, Asperger disorder, and pervasive developmental disorder (PDD) not otherwise specified, is a condition involving deficits in social communication, as well as the presence of restricted and repetitive patterns of behavior, interests, or activities.[1]

EPIDEMIOLOGY, NATURAL COURSE OF THE DISEASE, AND PROGNOSIS

Developmental disorders are common in the community, affecting as many as 15% of children in the U.S., based on parent report.[2] Collectively, developmental disorders are nearly twice as likely in boys and children insured by Medicaid, relative to girls and those insured by private insurance, respectively.[2] Additionally, a higher prevalence of developmental disorders is reported by families with incomes below the federal poverty level and with lower maternal education (any educational attainment less than a college degree).[2]

For ID and GDD, the overall prevalence is estimated to be between 1% and 3% of the population, though with considerable variability depending on how the diagnosis is defined and reported in the literature.[3,4] Intellectual disability is more prevalent in males versus females, and in low- and middle-income countries relative to high-income countries.[3]

ASD is increasing in prevalence, with the Centers for Disease Control and Prevention reporting about 1 in 68 children (1.47%) being identified with the disorder.[5] Although around one-third of children with ASD may also qualify for intellectual disability, the proportion of children with average or above average intelligence being diagnosed with ASD has been steadily increasing over the years and may explain some of the increase in overall ASD prevalence.[5] The proportion of children with ASD who are boys has consistently been 4 to 5 times that of girls.[5] In the United States, around 30% of children with ASD have some level of ID.[5]

The course and prognosis of both ID and ASD vary considerably depending on the severity of the deficits, the impact of comorbid medical and psychiatric conditions, and the access to services and treatments. Many individuals will go on to live rich and fulfilling lives, with minimal required assistance in daily life functioning, though some will require constant supervision in supportive group housing, and assistance for basic tasks of daily living.

PATHOPHYSIOLOGY: DISEASE ETIOLOGY, ANATOMY, AND PHYSIOLOGY

Many different known and unknown genetic and environmental factors can lead to the impairment in early brain development associated with developmental disorders.

For both ID and ASD, risk factors include preterm birth, low birth weight, small for gestational age, and low Apgar scores, though all of these are associated more strongly with ID.[6] For ID specifically, risk factors may differ depending on the severity of ID. Studies have shown risk factors for mild ID to include mothers under the age of 20 years or older than 30 years, paternal age greater than 40 years, increasing birth order, increasing social disadvantage, maternal education less than high school, being part of a multiple birth, and being second or later in the birth order.[7,8] The risk of severe ID was consistently increased with increasing maternal age and decreasing level of maternal education.[7] For ASD without ID, additional risk factors include mothers aged 35 years or older, first-born infants, male infants, and increasing socioeconomic advantage.[8]

In only about half of all cases of ID can a specific etiology be identified and may include genetic anomalies, intrapartum asphyxia, cerebral dysgenesis, and environmental causes.[9] In only about 30% of children with ASD can an identifiable genetic etiology be determined.[10] Although inherited genetic forms of ID likely represent a minority of identified cases, ASD on the other hand is widely considered to be one of the most heritable neuropsychiatric conditions with heritability estimates of 60% to 90%.[11] For parents with one child with ASD, the recurrence rate in future siblings is thought to be 5% to 20%, with higher rates if the original child with ASD is female.[12] This recurrence rate increases to about 33% if a family already has two children with ASD.[12]

For inherited genetic anomalies, X-linked gene defects account for 10% to 12% of all ID cases in males, with fragile X syndrome being the most common.[13] Fragile X syndrome, marked by a CGG triplet repeat expansion in the FMR1 gene on the X chromosome, is also the most common single-gene cause of ID, accounting for about 0.5% to 3% of individuals with ID,[14] and ASD, accounting for around 1% to 3% of cases.[10,15] Single-gene disorders, some heritable like fragile X syndrome, account for about 5% to 7% of ASD cases and include PTEN macrocephaly syndrome (~1%), tuberous sclerosis complex (~1%), and Rett syndrome (~1%).[10,15] Other inherited causes of ID and ASD include inherited metabolic disorders, such as phenylketonuria, adenylosuccinate lyase deficiency, and Smith–Lemli–Opitz syndrome.[15] Although inherited metabolic disorders are relatively rare, accounting for only 1% to 5% of cases of ID, the potential for positive prognosis with treatment is high.[4]

Other genetic anomalies that can lead to ID and ASD include noninherited, or de novo, single-gene mutations, chromosomal aberrations, and imprinting/epigenetic disorders.[14] Chromosomal aberrations may account for up to 25% of individuals with ID, about 8% or 9% of which is due to trisomy 21, or Down syndrome, the most common known cause of ID.[14,16] Prader–Willi and Angelman syndromes, both associated with developmental delays, are two examples of disorders involving imprinted genes.

Environmental causes of ID range in the literature from 2% to 13% and include antenatal toxin exposure (e.g., fetal alcohol spectrum disorders), antenatal infection (e.g., TORCH infections), and early severe psychosocial deprivation.[17,18] Environmental causes of ASD include first trimester intrauterine exposure to valproic acid, thalidomide, misoprostol, the organophosphate insecticide chlorpyrifos, and phthalates, in addition to first trimester rubella infection.[19] While receiving much scrutiny, multiple studies have shown no support linking vaccines to autism.[20]

CLINICAL PRESENTATION

Developmental disorders are typically recognized clinically once it becomes clear that a child is delayed in meeting one or more developmental milestones. Primary care providers have been tasked by the American Academy of Pediatrics (AAP) to assess development at every routine preventative visit throughout childhood.[21] Additionally, the AAP encourages pediatricians to use standardized developmental screening tools (e.g., Ages and Stages Questionnaires—ASQ and Parents' Evaluation of Developmental Status—PEDS) at the 9-, 18-, and 24- or 30-month visit, and an autism-specific screening tool at the 18- and 24-month visits (e.g., Modified Checklist for Autism in Toddlers—MCHAT).[21,22] Once concerns are raised by routine surveillance or screening measures, children should be referred to early intervention and early childhood programs, as well as to developmental specialists, when indicated.[21]

Early recognition of developmental disorders depends on children having access to preventative medical care, and almost 25% of children with special health care needs might not have that access.[23] The nature and severity of the developmental deficits also contribute to the age at recognition. The sensitivity of developmental and autism screening measures rarely reaches 0.9,[21] and so relatively mild developmental deficits may go undetected. For children with ASD, the mean age of diagnosis has been around 53 months,[5] though children with intellectual disability and those diagnosed with autistic disorder are typically diagnosed earlier; children with higher IQ scores and those eventually diagnosed with Asperger disorder, whose limitations do not include communication delays, are typically diagnosed later.[5] Some individuals with particularly subtle deficits may not be diagnosed until adulthood. Individual symptoms that may lead to an earlier diagnosis of ASD may include severe language deficits, hand flapping, toe walking, and sustained odd play.[24]

DIAGNOSIS

ID is defined by both the American Psychiatric Association and the American Association on Intellectual and Developmental Disability (AAIDD) as a disorder with deficits in intellectual and adaptive functioning in conceptual, social, and practical domains.[1,25] The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-V) requires that the disability has onset "during the developmental period," whereas the AAIDD requires the disability to start before age 18 years. Intellectual functioning is assessed clinically and by standardized tests of intelligence, like IQ testing (e.g., Wechsler Intelligence Scale for Children and the Stanford–Binet Intelligence Scale), with a cutoff being two standard deviations below the mean for the general population, or a score of around 65 to 75, for disability.[1] Older references focused diagnosis primarily around IQ scores, and subcategories of intellectual disability (then called mental retardation) were set to specific IQ scores.[1] Current methods of diagnosis focus more on measures of adaptive functioning, because this is more relevant to planning treatment and supports. Adaptive functioning is also assessed clinically or with standardized tests of adaptive functioning (e.g., Vineland Adaptive Behavior Scales). Subcategories for intellectual disability in the DSM-V are now based on levels of adaptive functioning, mild, moderate, severe, and profound. As standardized testing for intellectual and adaptive functioning is typically valid for children above the age of 5 years, for children younger than 5 years, the diagnosis of GDD is used and describes significant delays in two or more developmental domains, including gross/fine motor, speech/language, cognition, social/personal, and activities of daily living.[26]

ASD is defined by the DSM-V as the presence of persistent impairment in reciprocal social communication and social interaction, and restricted, repetitive patterns of behavior, interests, or activities, present from early childhood, and impairing everyday functioning (Table 88-1).[1] The diagnosis is made clinically, though standardized behavioral diagnostic instruments, including caregiver interviews, questionnaires, and clinician observation measures (e.g., Autism Diagnostic Interview and Autism Diagnostic Observation Schedule), are available to potentially assist in diagnosis.

Table 88-1

DSM-V Criteria for ASD[1]

A. Persistent deficits in social communication and social interaction across multiple contexts, as manifested by all of the following, currently or by history (examples below):
1. Deficits in social–emotional reciprocity, ranging, for example, from abnormal social approach and failure of normal back-and-forth conversation; to reduced sharing of interests, emotions, or affect; to failure to initiate or respond to social interactions.
2. Deficits in nonverbal communicative behaviors used for social interaction, ranging, for example, from poorly integrated verbal and nonverbal communication; to abnormalities in eye contact and body language or deficits in understanding and use of gestures; to a total lack of facial expressions and nonverbal communication.
3. Deficits in developing, maintaining, and understanding relationships, ranging, for example, from difficulties adjusting behavior to suit various social contexts; to difficulties in sharing imaginative play or in making friends; to absence of interest in peers.

B. Restricted, repetitive patterns of behavior, interests, or activities, as manifested by at least two of the following, currently or by history (examples below):
1. Stereotyped or repetitive motor movements, use of objects, or speech (e.g., simple motor stereotypies, lining up toys or flipping objects, echolalia, idiosyncratic phrases).

2. Insistence on sameness, inflexible adherence to routines, or ritualized patterns or verbal nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat food every day).
3. Highly restricted, fixated interests that are abnormal in intensity or focus (e.g., strong attachment to or preoccupation with unusual objects, excessively circumscribed or perseverative interest).
4. Hyper- or hyporeactivity to sensory input or unusual interests in sensory aspects of the environment (e.g., apparent indifference to pain/temperature, adverse response to specific sounds or textures, excessive smelling or touching of objects, visual fascination with lights or movement).

Severity is based on social communication impairments and restricted, repetitive patterns of behavior [Level 1 (requiring support), Level 2 (requiring substantial support), Level 3 (requiring very substantial support)]

C. Symptoms must be present in the early developmental period (but may not become fully manifest until social demands exceed limited capacities, or may be masked by learned strategies in later life).

D. Symptoms cause clinically significant impairment in social, occupational, or other important areas of current functioning.

E. These disturbances are not better explained by intellectual disability (intellectual developmental disorder) or global developmental delay. Intellectual disability and autism spectrum disorder frequently co-occur; to make comorbid diagnoses of autism spectrum disorder and intellectual disability, social communication should be below that expected for general developmental level.

After a child is identified to have a developmental disorder, further diagnostic workup is warranted to identify an etiologic cause, because some causes may be treatable (e.g., metabolic disorder), some may inform of other potential comorbid medical problems (e.g., cardiac conditions in Down syndrome and fragile X syndrome), and some may help inform parents of risks for future children. This further etiologic workup should include a thorough medical history (including prenatal and birth history), a family history going back three or more generations, and a physical and neurologic examination focused on findings consistent with recognizable syndromes.[4]

If children with ID or GDD still do not have a known etiologic cause after this workup, they should be referred for chromosomal microarray and possibly screening for inborn errors of metabolism given the treatable nature of some metabolic disorders.[4] The American College of Medical Genetics and Genomics proposes that in the event of a diagnosis of ASD without a known cause despite the above workup, all children should undergo chromosomal microarray, those children with clinical indicators should undergo metabolic or mitochondrial testing, fragile X testing should be performed for all boys, MECP2 (Rett syndrome) testing should be performed in all girls, PTEN testing in children with macrocephaly, and neuroimaging only if specific clinical indicators (e.g., seizures, regression, history of stupor/coma, microcephaly).[27]

CASE 88-1

QUESTION 1: L.B. is a 3-year-old boy who is brought to his pediatrician for a well-child visit. During the behavioral health screening, his mother notes that L.B. speaks very few words, does not express many different emotions on his face, does not seem to share enjoyment in activities, and remains fairly unmotivated to interact with other children in daycare. He has more recently been making repetitive loud "woop"-ing sounds that are nonprompted and occur multiple times per day. He also becomes quite aggressive during any transitions. During the visit, the pediatrician completes the Childhood Autism Rating Scale, Second Edition (CARS-2). The result is a score of 32, suggesting a diagnosis of autism spectrum disorder (ASD). The pediatrician refers L.B. and his mother to a developmental pediatrician, who specializes in ASD, for further evaluation. After a thorough evaluation, and review of the differential diagnosis, L.B. is given a diagnosis of ASD and is referred for applied behavior analysis (ABA) services.

What signs and symptoms of autism spectrum disorder does L.B. demonstrate?

Based on the DSM-5 criteria for ASD, L.B. is showing persistent deficits in social communication and social interaction in multiple settings, as demonstrated by his deficits in nonverbal communication (poor facial expressions), lack of relationship building with children, and poor social–emotional reciprocity (lack of shared enjoyment). L.B. also demonstrates restricted, repetitive patterns of behavior with his stereotyped "woop"-ing noises and his inflexible insistence on sameness, with aggression associated with transitions.

OVERVIEW OF TREATMENT

Therapy and Psychosocial Interventions

Individuals with ID or ASD can benefit from many different services to help with issues of communication, social skills, sensory integration, behavior modification, gross and fine motor, executive functioning, and adaptive functioning. Most of these services are provided to children through the public education system, at no cost to the families, as ensured by the Individuals with Disabilities Education Act (IDEA). The IDEA provides all states with grants to provide early intervention services for children with developmental delays under the age of 3. Services vary between states, though each child and family are evaluated and given an Individualized Family Service Plan (IFSP), which spells out the services to be provided, which may include, but are not limited to, physical therapy, occupational therapy, speech and language therapy, and behavioral therapy. For children reaching the age of 3 years, and still eligible for specialized education, an Individualized Education Plan (IEP) is drafted, which outlines the services to be provided in the school setting, starting in preschool. IEP services could include all of the same types of services as above, as well academic support, social skills groups, social pragmatics counseling, vocational training, and emotional counseling. IEPs are required to be reevaluated every 3 years, with updated testing and evaluation. Families must consent to both IFSPs and IEPs, and if they disagree with the supports proposed, there is a process by which they can appeal to have changes made.

Despite the services assured by the IDEA, children and families with developmental disabilities also often receive psychosocial services in their communities. In fact, in the 2011 Survey of Pathways to Diagnosis and Services, almost two-thirds of children with ASD and/or ID were receiving a community-based service.[28] The odds of using any school- or community-based service were almost 8 times more likely for children with ASD, and over 9 times more likely for children with ID, compared to children without those respective diagnoses.[28]

To address the core symptoms of ASD, which include social communication deficits and repetitive, restricted behaviors and interest, the most prevalent treatment modality has been applied behavior analysis (ABA). ABA is a behavioral therapy rooted in the concepts of operant conditioning, in which an antecedent leads to a behavior, which results in a consequence. In ABA, preferred behavior, such as an appropriate social response, is reinforced with an incentive. Classic ABA employs the use of discrete trial training (DTT), in which specific skills are broken down into discrete components and systematically taught in highly structured settings, often using incentives like food and stickers. Critics of this form of ABA worry that children with ASD are unlikely to apply the learned skills outside of the trial setting. As a result, multiple different therapy approaches have been created, such as Pivotal Response Therapy and the Early Start Denver Model, both derivations of ABA, and the Developmental, Individual-differences, Relationship-based (DIR) Floortime approach, which all operate in more naturalistic settings, focus more on building child initiation and motivation, and employ natural incentives like positive affect and affection. The research evidence to support such interventions for children and young adults with ASD varies widely, as is explored in Wong et al.'s [29] comprehensive recent review. Operant conditioning though, and the principles of manipulating antecedents, behavior, and reinforcements, remains the mainstay for the treatment of aggressive behaviors in individuals with developmental disabilities.[30]

Individuals with ID often require the same types of interventions as individuals with ASD, though perhaps with a stronger emphasis on adaptive functioning training, and building skills of independent living. Likewise, for individuals with ID, the evidence base for psychological interventions is varied. One recent review and meta-analysis of psychological therapies for individuals with ID showed that in the literature, individual therapy seems to be superior to group interventions, and moderate to large effect sizes exist for therapy for depression and anger, though there is no evidence that therapy has an effect on interpersonal functioning.[31]

Pharmacologic Interventions

The evidence supporting psychopharmacologic interventions in individuals with ID/ASD is relatively limited. There are only a few large double-blind, randomized, placebo-controlled trials (RCTs), many of which were funded by, or affiliated with, the manufacturers of the particular study medications. Most of the existing RCTs are for individuals with ASD and are of children and adolescents, likely, in part, because of the complications involved in consenting adults with ID/ASD to participate in research. Additionally, the targets for medication intervention with the strongest research evidence are behaviors, which relay little about any possible underlying emotional etiology for the individual.

Despite the limitations of the evidence, clinicians working with individuals with ID/ASD know that medications can often serve a very important role as part of a comprehensive treatment plan. Although much of the literature is of studies of children with ASD, it should be noted that a large percentage of these studies contained many individuals with comorbid ID (76%,[32] 71%,[33] 53%,[34] mean IQ, 63[35,36]). However, the literature confirms that individuals with ID/ASD are more sensitive to adverse events from medications compared to their neurotypical peers, and therefore, pharmacologic interventions should be performed with caution.

At the time of this writing, there are no medications approved by the U.S. Food and Drug Administration (FDA) to treat any of the core diagnostic elements of ID/ASD. The target symptom behaviors with the most research evidence include hyperactivity, irritability, repetitive behaviors, and self-injurious behavior. As anxiety disorders are the most common comorbid psychiatric conditions in individuals with ID/ASD, anxiety/depression is another frequent target for psychopharmacologic intervention, though with considerably less research support. Sleep disturbances are also remarkably common in individuals with developmental disabilities and often are a target for medication intervention.

Hyperactivity

Individuals with ID/ASD have high rates of comorbid ADHD, with literature in children with ASD showing prevalence rates of about 30% for children derived from community, nonclinical, populations (28%[37] and 31%[38]), and 41% to 78% for children evaluated in the clinical setting.[39] The mainstay of treatment for symptoms of ADHD in individuals with ID/ASD, like their neurotypical peers, includes stimulants, α_2 agonists, and atomoxetine.

Stimulants

Stimulants are a group of medications derived either from methylphenidate or amphetamine that act by increasing the amount of dopamine and norepinephrine in the neuronal synaptic cleft. This increase in dopamine and norepinephrine is the result of blocking the reuptake of dopamine and norepinephrine (methylphenidate and amphetamine) and increasing the release of dopamine and norepinephrine (amphetamine).

Reichow et al.,[40] in their recent meta-analysis of pharmacologic treatments of symptoms of ADHD in children with PDD, found four RCTs of stimulant medications. All four RCTs studied methylphenidate and found it to be superior to placebo for the treatment of global ADHD symptomatology and specifically hyperactivity. In the largest of the four RCTs (n = 66),[41] effect sizes for hyperactivity and impulsivity symptoms were greater than for inattention symptoms (0.77 vs. 0.60 for parent rating; 0.48 vs. 0.35 for teacher rating).[35]

The effect size for the treatment of ADHD symptoms in children with PDD (0.67 for methylphenidate),[40] however, was lower than estimates in a meta-analysis of stimulant treatment of typically developing children with ADHD (0.77 for methylphenidate and 1.03 for amphetamine).[42] In the study conducted by the Research Unit on Pediatric Psychopharmacology (RUPP) group,[41] 49% of children experienced a therapeutic response, compared to 69% in the Multimodal Treatment Study of Children with ADHD (MTA), which studied mostly neurotypical children (ID was an exclusion criteria, and ASD was not mentioned as a comorbid diagnosis in any participants).[43]

Adverse events were more common in children with PDD treated with methylphenidate versus placebo, with increased rates of decreased appetite, insomnia, depressive symptoms, irritability, and social withdrawal.[40] Rates of adverse events with methylphenidate were also larger in children with PDD compared to typically developing children, as evidenced by 18% of RUPP study participants[41] discontinuing the medication due to adverse events (primarily irritability), compared to 1.4% in the MTA study.[43]

Mean dosage in the four RCTs ranged from 0.29 to 0.45 mg/kg/dose.[40] Secondary analysis of the RUPP study data showed that methylphenidate doses of 0.25 and 0.5 mg/kg/dose were more consistently effective for treating ADHD symptoms than the lower 0.125 mg/kg/dose.[35] The highest dose used in the RUPP study was 0.625 mg/kg/dose, compared to the MTA study, in which the highest dose used was 0.8 mg/kg/dose.[41]

Daily methylphenidate doses may be titrated weekly, until an optimal dose is obtained. Improvement in symptoms should be noted within the first week.[44]

Overall, the research literature shows that methylphenidate can be used to improve ADHD symptoms, especially hyperactivity, in children with PDD, though with lower effect sizes, lower tolerated doses, and more risk of adverse effects than children without developmental disabilities.

Although no RCTs have been conducted studying the effects of amphetamine-derived stimulants for the treatment of ADHD in children with ASD, consensus guidelines suggest that amphetamine salts can be an option for children demonstrating insufficient benefit or dose-limiting adverse events from methylphenidate.[45]

α_2 Agonists

Although the exact mechanism in ADHD is unknown, α_2 agonists are thought to work by stimulating the α_2 adrenoceptors on norepinephrine-containing neuron cell bodies in the locus coeruleus which modulates the tonic and phasic firing to the prefrontal cortex. This allows the person to have increased attention on the desired task.[46]

α_2 Agonists include clonidine, a nonselective α_2 adrenergic receptor agonist, and guanfacine, a selective α_2A adrenergic receptor agonist. α_2 Agonists were initially marketed for the treatment of hypertension, though have been shown to also improve symptoms of ADHD.

For clonidine, one small study ($n = 8$)[47] was identified by Reichow et al.[40] looking at clonidine versus placebo for the treatment of ADHD in children with PDD. Although the original study found no statistically significant results, the effect size calculated by Reichow et al.[40] for improvement in ADHD symptoms and irritability was in the medium range (γ = 0.51 and 0.64, respectively) and smaller for improvements in hyperactivity (γ = 0.30) and stereotypic behavior (0.24). The authors of the original study[47] report increased rates of hypotension and drowsiness in some children who took clonidine. Mean dosage ranged from 0.15 to 0.20 mg/day.

One small pilot RCT ($n = 11$) looking at guanfacine treatment in children with developmental disabilities showed statistically significant reductions in hyperactivity subscales and global rating of improvement, with 5 of the 11 participants deemed to be responders.[48] In this study, adverse events included drowsiness, irritability, and enuresis, as well as diarrhea, constipation, and social withdrawal; additional adverse events from an open-label study of guanfacine in children with PDD include sleep disturbance (insomnia or midsleep awakening).[49] Doses in both studies ranged from 1 to 3 mg/day.

Overall, a small collection of literature suggests that clonidine and guanfacine may be beneficial for the treatment of ADHD symptoms in children with ASD/ID, with similar adverse events as reported in neurotypical children, though more evidence is needed to draw any more extensive conclusions about the use of these medications in the ID/ASD population.

Atomoxetine

Atomoxetine is a medication for ADHD that acts by inhibiting the reuptake of norepinephrine, therefore increasing the amount of norepinephrine in the synaptic cleft. Dosing is generally once daily, with adjustments after a minimum of 3 days to a target daily dose. Clinical benefit has been noted within the first 1 to 2 weeks.[50]

Reichow et al.'s[40] meta-analysis found two RCTs comparing atomoxetine to placebo in children with PDD, though only the larger of the two ($n = 97$)[51] showed statistically significant benefits for the treatment of global ADHD symptoms and hyperactivity (effect sizes calculated by Reichow et al.[40] of $\gamma = 0.83$ and γ 0.80, respectively). In this study by Harfterkamp et al.,[51] changes in the subscales of inattention and oppositional behavior did not reach statistical significance for children on atomoxetine compared to placebo.

Children with PDD in the Harfterkamp et al.[51] study demonstrated increased rates of nausea, decreased appetite, and early morning awakening compared to study participants taking placebo. Mean dosage in the two studies was 1.2 mg/kg/day[51] and 44.2 mg/day.[52] This dosing is perhaps only slightly lower than other large studies of atomoxetine in children with ADHD without developmental disorders (mean final atomoxetine dose was 1.45 mg/kg/day, 53.0 mg/day[53]), though documentation from the drug manufacturer's studies, of presumably mostly neurotypical children with ADHD, indicates no additional benefits for doses above 1.2 mg/kg/day.[50]

Similar to the α_2 agonists, it seems that atomoxetine shows benefits in the literature for addressing ADHD symptoms in children with PDD, particularly for hyperactive symptoms, with similar dosing and adverse events to children with ADHD without developmental disorders.

Other Medications

Tricyclic antidepressants (TCA), which primarily act as serotonin–norepinephrine reuptake inhibitors (SNRIs), had been a part of older treatment algorithms for the treatment of ADHD in typically developing children[54] and, as a result, have also been studied in children with ASD. In Gordon et al.'s crossover RCT of clomipramine and desipramine versus placebo[55] (5 weeks each intervention), both drugs were significantly superior to placebo for reducing the hyperactivity domain of the Children's Psychiatric Rating Scale (CPRS) Autism Relevant Subscale, though no different from each other. TCAs are known for adverse effects, primarily antimuscarinic in nature, which includes dry mouth, blurred vision, decreased gastrointestinal motility, and urinary retention. TCAs can also cause irregular heart rhythms, tachycardia and hypotension, and should be used in caution in patients with preexisting cardiac conditions and can be fatal with just small excesses in dose. TCAs are also highly metabolized by the cytochrome P450 hepatic enzymes, including 3A4 and 2D6. Therefore, inhibitors of these enzymes can lead to increased concentrations and higher risk of side effects including cardiac abnormalities.

Although antipsychotic medications are not typically part of the treatment algorithm for ADHD in children with typical development,[54,56] studies of risperidone and aripiprazole for the treatment of children with ASD and irritability/aggression symptoms did show statistically significant improvement in hyperactivity subscales (Risperidone[32–34]; Aripiprazole[57,58]). As a result, atypical antipsychotics are part of a treatment algorithm developed by the Autism Speaks Autism Treatment Network Psychopharmacology Committee Medication Choice Subcommittee for symptoms of ADHD in individuals with ASD, if they have not shown adequate improvement from stimulants, atomoxetine, and α_2 agonists.[45]

Other medications, which have not yet been included in standard practice, though have shown some promising evidence for improvement in hyperactivity symptoms in RCTs of children with ASD, include omega-3 fatty acids,[59] tianeptine,[60] and adjunctive pentoxifylline[61] and topiramate,[62] when each added to risperidone.

CASE 88-1, QUESTION 2: L.B., now 5 years of age, has been receiving ABA services for nearly 2 years and has been progressing well. At home though, L.B. has become increasingly disobedient and hyperactive. In school, his teachers note that he is inattentive, wandering around the classroom and staring out the windows. In addition, during story time and craft time, he is disruptive and hyperactive, running around the room. In response, L.B.'s pediatrician facilitates an increase in the number of hours of in-home ABA services, whose providers also work with L.B.'s parents' teaching behavioral management techniques. The pediatrician also recommends certain classroom modifications to help with attention. This, however, does not reduce the outbursts or inattentive and hyperactive behavior, both at home and school. The pediatrician believes that a trial of pharmacotherapy may be helpful. The pediatrician consults you, the clinical pharmacist, to discuss an appropriate treatment plan.

What pharmacotherapy and formulation would be most appropriate for L.B.'s target symptoms?

Clinical trials have shown that stimulants can be a very effective treatment option for children with attention-deficit/hyperactivity disorder (ADHD). The American Academy of Child and Adolescent Psychiatry (AACAP) and the American Academy of Pediatrics (AAP) recommend the use of methylphenidate, over that of amphetamines or nonstimulant medication, in preschool children where behavioral modification therapy has not been adequate. The metabolism of methylphenidate in preschool children is slower than that of older children, and therefore the starting dose is lower, and the optimal dose is likely lower than in older children.

Based on this information, you recommend starting L.B. on methylphenidate IR solution 1.25 mg twice daily, with an increase to 2.5 mg twice daily on day 3, with subsequent dose increases every 3 days to reduce target symptoms, up to a maximum of 7.5 mg 3 times daily. You recommend that the parents keep a journal of the responses and possible experienced adverse effects during this period with a report back to the pediatrician at the end of the week.

Irritability/Aggression

Irritability/aggression is the pharmacologic target behavior with the most robust RCT evidence in children with ASD. Most of this evidence comes from four large RCTs of either risperidone or aripiprazole.[32,33,57,58] In this context, risperidone and aripiprazole are the only two medications with FDA approval for the use in individuals with developmental disabilities. Specifically, each has an FDA-approved indication for the treatment of autistic disorder-associated irritability in children and adolescents (risperidone—age 5–17 years; aripiprazole—age 6–17 years).

Risperidone

Both McCracken et al.'s[32] and Shea et al.'s[33] studies of risperidone were 8 weeks in duration, in a population of children and adolescents with either solely autistic disorder,[32] or mostly autistic disorder[33] (70% of study population had autistic disorder; rest were diagnosed with either PDD NOS, Asperger disorder, or childhood disintegrative disorder), and with mostly comorbid ID (64% of study population[33]; 81% of study population[32]). Both showed risperidone to have statistically significant improvements, compared to placebo, in the Irritability subscale of the Aberrant Behavior Checklist (ABC-I) (ABC-I is a 15-item subscale that includes items such as "injures self," "physical violence to self," "aggressive to other children and adults," "irritable," "temper outbursts," "depressed mood," "mood changes," and "yells" or "screams" inappropriately; individual items are rated on a scale ranging from 0—not at all a problem, to 3—severe),[58] as well as the ABC subscales for hyperactivity and stereotypy. The subscales for social withdrawal and inappropriate speech only showed statistically significant improvements for risperidone compared to placebo in Shea et al.'s study.[33] The definition of "response" was different in each study. In McCracken et al.,[32] positive response was defined as at least a 25% decrease in the ABC-I score and a rating of much improved or very much improved on the Clinical Global Impression rating scale (CGI), improvement subscale (CGI-I). With this definition, 69% were responders in the risperidone group and 12% in the placebo group. In Shea et al.,[33] a responder was defined as having a 50% or greater decrease from baseline in at least two of the five ABC subscales with none of the other subscales presenting a 10% or larger increase. With this definition, 69% of subjects in the risperidone group were responders, compared to 40% in the placebo group.

In McCracken et al.,[32] study participants in the risperidone group, compared to placebo, experienced significantly higher rates of increased appetite, fatigue, drowsiness, dizziness, and drooling, with trends of increased rates of tremor, tachycardia, and constipation (P = 0.06). In a 16-week open-label extension of McCracken et al.'s[32] study, the most common adverse events were excessive appetite, enuresis, tired during day, dry mouth, excess saliva, rhinitis, coughing, and anxiety.[63] Risperidone-treated participants in Shea et al.'s study[33] experienced significantly greater increases in weight, pulse rate, and systolic blood pressure and had a significantly higher rate of reported somnolence (73% risperidone vs. 8% placebo). Extrapyramidal symptoms (EPS) were endorsed by 28% of the risperidone-treated participants in Shea et al.,[33] compared to 13% in the placebo group. Mean weight gain in both 8-week studies for those taking risperidone was 2.7 kg. Mean final daily risperidone dose was 1.8[32] and 1.48 mg,[33] which is in contrast to the mean final daily risperidone dose of 2.8 mg in a large RCT of the antipsychotic treatment of early-onset schizophrenia and schizoaffective disorder in children and adolescents (ID was an exclusion criteria).[64]

Although prolactin was not mentioned in either 8-week study of risperidone, a long-term follow-up of the McCracken et al.[32] study confirmed that risperidone treatment was associated with a 2- to 4-fold increase in serum prolactin levels.[65]

McDougle et al.'s[66] study of risperidone in adults with ASD showed similarly beneficial findings for the reduction in aggressive behavior, compared to placebo, and common adverse events also included sedation and weight gain. The mean final daily dose of risperidone was 2.9 mg, which is in contrast to the mean daily dose of risperidone of 3.9 mg in a large RCT of adults with schizophrenia.[67]

Aripiprazole

Both Marcus et al.'s[58] and Owen et al.'s[57] studies of aripiprazole versus placebo in children and adolescents with autistic disorder were 8 weeks in duration. Prevalence of comorbid ID was not mentioned in either study. Both studies showed statistically significant improvement in children treated with aripiprazole, compared to placebo, for ABC-I, CGI-I, as well as ABC subscales of hyperactivity and stereotypy. Although Owen et al.'s[57] flexible dosing schedule showed statistically significant improvements in the ABC subscale for inappropriate speech with aripiprazole versus placebo, in Marcus et al.'s[58] fixed-dose study, only the 15 mg/day dose of aripiprazole showed statistically significant improvement in inappropriate speech. Neither study showed statistically significant improvement for aripiprazole, versus placebo for the ABC lethargy/social withdrawal subscale. Both studies defined response as at least a 25% reduction from baseline to endpoint in the ABC-I subscale and a CGI-I score of 1 (very much improved) or 2 (much improved) at endpoint. With this definition, response rate was 52.2% for aripiprazole in Owen et al.'s study[57] (14.3% for placebo) and although response rates for each dose of aripiprazole (5 mg—55.8%*, 10 mg—49.2%, 15 mg—52.8%) were higher than placebo (34.7%) in Marcus et al.'s study,[58] only the response rate at 5 mg/day separated from placebo with statistical significance.

In Marcus et al.'s study,[58] the three most common adverse events leading to discontinuation of aripiprazole were sedation, drooling, and tremor, none of which were reported in the placebo group. The most common adverse events reported in the aripiprazole group of Owen et al.'s study[57] were fatigue, somnolence, vomiting, increased appetite, and sedation. In Owen et al.,[57] 14.9% of aripiprazole-treated subjects (vs. 8% for placebo) endorsed EPS symptoms, with the most common being tremor (8.5%). In Marcus et al.,[58] EPS symptoms were reported at roughly twice the rate in all aripiprazole doses (5 mg/day—23.1%, 10 mg/day—22.0%, and 15 mg/day—22.2%) compared to placebo (11.8%), the most common of which were tremor and extrapyramidal disorder. Aripiprazole was associated with statistically significant gains in weight compared to placebo after 8 weeks, with the mean weight gain on aripiprazole in Owen et al.[57] being 2.0 kg, and for Marcus et al.,[58] 1.3 kg (5 mg/day), 1.3 kg (10 mg/day), and 1.5 kg (15 mg/day). Interestingly, both studies showed aripiprazole to have statistically significant reductions in prolactin levels compared to placebo. Mean final daily dosing for aripiprazole in Owen et al.[57] was 8.9 mg/day. In a 52-week open-label follow-up study of participants from both Owen et al.[57] and Marcus et al.,[58] as well as newly enrolled subjects, mean final daily dosing of aripiprazole was 10.6 mg/day.[68] In a 2-month RCT of aripiprazole versus risperidone in children with ASD, the mean final daily dose of aripiprazole was 5.5 mg.[69] Manufacturer recommended daily dosing of aripiprazole in pediatric patients with schizophrenia or bipolar disorder is 10 mg/day.[70]

Overall, the literature shows that risperidone and aripiprazole, in doses likely lower than that used in children with schizophrenia or bipolar disorder, can be used effectively to reduce symptoms of irritability and aggressive behavior in children and adolescents with ASD, though treatment should be monitored closely for relatively common adverse events of sedation, weight gain, and EPS. Of note, although risperidone has been shown to consistently increase prolactin levels, aripiprazole was shown to consistently lower prolactin levels.

Although risperidone and aripiprazole are the two antipsychotic medications with FDA approval for the treatment of irritability in children with ASD, other typical and atypical antipsychotics have

also demonstrated benefits for treating symptoms of irritability in children with ASD. Haloperidol, dosed in the range of 0.5 to 4.0 mg/day, has shown benefits in four RCTs and two long-term follow-up studies, though with significant rates of dyskinesia (34%).[71] One RCT supports the benefits of pimozide, one RCT supports the use of olanzapine, and either open-label studies or case reports exist to support the benefits of olanzapine, clozapine, quetiapine, ziprasidone, and paliperidone.[72] A head-to-head comparison RCT of risperidone and haloperidol in children with autistic disorder showed risperidone to be significantly more effective than haloperidol at reducing aberrant behavior and symptoms of PDD.[73] An RCT though comparing risperidone, haloperidol, and placebo for the treatment of aggression in adults with ID showed all three treatment arms to decrease aggression, though no significant difference between any of the three treatments.[74]

Other Medications

VALPROATE

Two RCTs of similar size (n = 30[75] and n = 27[36]) looked at valproate versus placebo in children and adolescents with ASD and irritability/aggression with somewhat conflicting results. Hellings et al.[75] found no significant difference in improvement of irritability or aggression (including ABC-I and CGI-I) between valproate and placebo after 8 weeks, whereas Hollander et al.,[36] after 12 weeks, showed valproate to be significantly superior to placebo at improving CGI-I and the rate of improvement of ABC-I. While in Hollander et al.,[36] no significant differences existed in adverse events between valproate and placebo, in Hellings et al.,[75] there was a significantly increased rate of endorsed appetite increase in the valproate group, and two individuals in the valproate group developed elevated ammonia levels, one with clinically associated symptoms. Both studies had target blood valproate levels (at least 50 mcg/mL,[36] 70–100 mcg/mL[75]).

Additional medications with either limited RCT data, open-label studies, or case reports to support its use for irritability in individuals with ASD include buspirone, clomipramine, clonidine, levetiracetam, memantine, mirtazapine, pioglitazone, topiramate (when added to risperidone), riluzole, sertraline, and trazodone,[72] as well as fluvoxamine[76] and lithium.[77] In Reichow et al. recent meta-analysis of medications for the treatment of ADHD symptoms in children with PDD, methylphenidate had moderate, though not statistically significant, benefits in treating irritability.[40]

CASE 88-2

QUESTION 1: C.Y., a 9-year-old girl with ASD has been well maintained on risperidone for the last 3 years. At the most recent checkup, the prescriber notes that she has gained ~25 lbs over the last 2 years (note that average weight gain for a 9-year-old child is approximately 5 lbs/year). The majority of weight gained seems to be in the abdominal area. Blood tests note an elevated hemoglobin A1C of 8.4%. The provider discusses diet and exercise, but C.Y.'s mother notes no change over the last few years. She believes her weight gain started with the addition of risperidone, which is now at 4 mg/day.

The prescriber asks you for a recommendation based on your knowledge of the metabolic profiles of atypical antipsychotics. You make the following recommendation.

Although risperidone and aripiprazole are not necessarily interchangeable, both are indicated for the treatment of irritability in children with ASD, and aripiprazole may convey less of a risk for weight gain than risperidone. This potential benefit may outweigh the potential risk of aripiprazole being less clinically efficacious than risperidone in some patients. In this context, you may recommend for the prescriber to decrease risperidone by 1 mg every other week, while starting aripiprazole 2 mg/day for 7 days followed by an increase to 5 mg daily. Additional 5 mg dose increases can be made weekly up to a maximum of 15 mg/day. C.Y. should be monitored for tolerability during both the cross-taper/titration period and beyond.

REPETITIVE BEHAVIORS

Numerous different types of medications have been studied for the treatment of repetitive behaviors in individuals with ASD. Selective serotonin reuptake inhibitors (SSRIs) and TCAs have been studied likely due to perceived similarities between the repetitive behaviors and compulsions exhibited in children with obsessive–compulsive disorder, as well as the clinical observation that repetitive behaviors may increase in children with PDD due to underlying anxiety. However, the literature is mixed to support the use of SSRIs or TCAs for this indication.

Selective Serotonin Reuptake Inhibitors

Two RCTs looking at SSRIs for children with ASD and repetitive behavior demonstrate conflicting results. Hollander et al.'s[78] crossover trial (n = 39, mean age, 8.2 years) showed that low-dose liquid fluoxetine was superior to placebo for treating repetitive behaviors, as measured by the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS) compulsion subscale, with a medium to large effect size (0.76), though did not separate from placebo for improvements in other aspects of global autism severity. In King et al.'s[79] large study of citalopram (n = 73) versus placebo (n = 76) to target repetitive behaviors in children with ASD, there were no statistically significant differences between citalopram and placebo in improvements in overall symptomatology (CGI-I) or repetitive behaviors on the modified CY-BOCS-PDD rating scale. An RCT of fluvoxamine versus placebo in adults with ASD (n = 15 each group), however, did show fluvoxamine to be significantly superior to placebo for improving repetitive thoughts and behavior.[76] [See below in anxiety/depression for more details on SSRI prescribing in children with ASD].

TCAs

Clomipramine was studied in Gordon et al.'s[55] RCT, in which it was shown to be significantly superior to both placebo and desipramine for the treatment of repetitive behavior in children with ASD as shown by the Modified CPRS OCD subscale, the modified National Institute of Mental Health (NIMH) OCD Scale, and the modified NIMH Global OCD and Anxiety scales. The mean final week daily dose of clomipramine was 152 mg; the mean final week clomipramine blood level was 235 ng/mL and desmethyl clomipramine level was 422 ng/mL. Overall adverse events were relatively minor, though in those taking clomipramine, one person had a seizure, and two had cardiac adverse events, one with a prolonged corrected QT interval (0.45 seconds) and the other with severe tachycardia (160–170 beats/minute), both of which resolved with reduction in dose. In Remington et al.'s[80] crossover RCT (7 weeks each intervention) comparing clomipramine to haloperidol in children with autistic disorder, the most striking finding was that only 37.5% of participants taking clomipramine finished the study (compared to 69.7% haloperidol and 65.6% for placebo), with adverse events contributing to discontinuation including behavioral problems, fatigue or lethargy, tremors, tachycardia, insomnia, diaphoresis, nausea or vomiting, and decreased appetite. The mean daily dose of clomipramine was 128.4 mg, range 100 to 150 mg.

Overall, for the reduction of repetitive behaviors, SSRIs, specifically fluoxetine, and TCAs, specifically clomipramine, may be helpful in children with ASD, though adverse events may be particularly limiting for clomipramine. For adults with ASD, SSRIs, specifically fluvoxamine, may be helpful in reducing repetitive behaviors.

Antipsychotics

Antipsychotics have shown the most robust evidence in reducing repetitive behaviors in children with ASD. Nearly all of the data to support antipsychotics for this purpose come from the same studies that targeted irritability. Both aripiprazole[57,58] and risperidone[32,33] were superior to placebo for reducing the score on the ABC Stereotypy subscale. In McDougle et al.'s[81] secondary analysis of the 8-week RUPP Risperidone trial,[32] risperidone resulted in significantly greater reductions, compared to placebo, in the scores on the modified compulsion subscale of the CY-BOCS (effect size, 0.55), and the sensory motor behaviors subscale of the Ritvo–Freeman Real Life Rating Scale (effect size, 0.45). Similar findings for risperidone's benefit for reducing repetitive behaviors have been found in adults with ASD, including McDougle et al.'s RCT,[66] which found statistically significant reductions in the modified version of the Y-BOCS (focusing only on repetitive behavior, not thoughts).

Stimulants

In Reichow et al. recent meta-analysis of medications for the treatment of ADHD symptoms in children with PDD, methylphenidate had moderate, though not statistically significant, benefits in treating stereotypies.[40]

Other Medications

Despite valproate demonstrating efficacy for the treatment of irritability in Hollander et al.'s study of children with ASD, it showed no significant improvement in repetitive behavior, compared to placebo.[36] One small RCT of 1.5 g/day of omega-3 fatty acids (fish oil n = 7, placebo n = 5) showed no significant difference compared to placebo in reduction of ABC Stereotypy, though effect size was 0.72.[59]

SELF-INJURIOUS BEHAVIOR

Depending on the rating scale or etiologic theory, self-injurious behavior is commonly thought of as either an act of aggression toward the self, or as a repetitive, stereotyped behavior. Consequently, pharmacologic approaches to the treatment of self-injury have been rooted in the approaches for the treatment of aggression or repetitive behavior. Self-injurious behavior has its own literature base though, with similar and dissimilar findings.

Typical and Atypical Antipsychotics

RCTs of typical antipsychotics for the reduction of self-injurious behavior in individuals with developmental disabilities have had mixed findings. There has been relatively unconvincing data for the benefit of haloperidol, fluphenazine, chlorpromazine, or thioridazine in reducing self-injurious behavior.[82] Risperidone is the atypical antipsychotic with the most robust RCT data for improving self-injurious behavior, with two relatively large RCTs in children with ID showing improvement in the self-injury/stereotypic subscale of the Nisonger Child Behavior Rating Form,[83,84] one of which was statistically significant,[84] and statistically significant reductions in self-injurious behavior in adults with ASD, as measured by the Self-injurious Behavior Questionnaire.[66] Similar to studies in children with ASD, weight gain and somnolence were markedly higher in children taking risperidone than placebo.

Antidepressants

Clomipramine has been shown to be effective in reducing self-injurious behavior, but again with significant adverse effects.[82] Fluoxetine has been shown to be effective at reducing compulsive skin picking in two RCTs,[85,86] and fluvoxamine has been effective for reducing repetitive behavior and aggression in adults with ASD.[76] Case reports and open-label studies have shown possible benefit for buspirone and paroxetine as well.[82]

Naltrexone

A recent systemic review of naltrexone used in adults with intellectual disability showed 8 out of 10 RCTs demonstrating a reduction in the frequency of self-injurious behavior.[87] More specifically, 50% of participants had improvement in self-injury, with improvement being more pronounced in individuals with severe and profound ID. Nine percent experienced minor adverse events, which included weight loss, loss of appetite, thirst, yawning, mild liver function test abnormalities, nausea, and tiredness. Dosing ranged from 0.5 to 2 mg/kg, and doses from 25 to 100 mg.

Overall, despite very limited evidence, it seems the literature supports the use of risperidone, naltrexone, and clomipramine for the reduction of self-injurious behavior in individuals with developmental disabilities. Additionally, fluoxetine and fluvoxamine may have benefits as well, though less well evidenced.

ANXIETY/DEPRESSION

Selective Serotonin Reuptake Inhibitors

Studies have found that individuals with PDDs are at high risk of comorbid anxiety and mood disorders.[37,38] Due to the demonstrated benefits and relative safety of SSRIs in typically developing children, SSRIs are very commonly prescribed for anxiety and depression in children with developmental disorders. No large double-blind, placebo-controlled trials have been conducted looking at the use of SSRIs for depression or anxiety in children with developmental disorders, though the literature has numerous case reports and open-label studies demonstrating SSRI-induced improvements in anxiety in individuals with ASD.[88,89]

Overall, the literature indicates that children with DD may respond differently to SSRIs compared to children with typical development. Three areas in which response to SSRIs may differ include risk of adverse events, dosing requirements, and target symptoms.

Adverse Events

Compared to children with typical development, children with DD are more likely to experience adverse events to SSRIs and specifically are more likely to endorse emotional/behavioral adverse events. The only two RCTs looking at SSRIs in children with DD evaluated fluoxetine[78] and citalopram[79] for the treatment of repetitive behaviors. In the crossover study (8 weeks each phase) of low-dose fluoxetine by Hollander et al.[78] (n = 39, mean age, 8.2 years), although there was no statistically significant difference in treatment-emergent adverse events between fluoxetine and placebo, the most common adverse events emerging during fluoxetine treatment were agitation (46%), insomnia (36%), and anxiety/nervousness (16%). Additionally, 16% of subjects required a dose reduction due to agitation while on fluoxetine, compared to 5% on placebo.

In contrast, both Geller et al.[90] and Liebowitz et al.[91] conducted RCTs of fluoxetine for the treatment of OCD in typically developing children (Geller: 13 weeks; n = 71 fluoxetine, 32 placebo; mean age 11.4 years/Liebowitz: 8-week acute phase; n = 21 fluoxetine, 22 placebo; mean age, 12–13). In Geller et al.,[90] there was no statistically significant difference in reported adverse events, and the most common adverse events reported in the fluoxetine group were headache (28%), rhinitis (27%), and abdominal pain (16%), with no reports of agitation. In Liebowitz et al.,[91] six adverse events occurred significantly more frequently in the fluoxetine group: palpitations, weight loss, drowsiness, tremors, nightmares, and muscle aches, and the most common adverse events reported by those taking fluoxetine were headache (52%), abdominal pain (43%), decreased appetite (38%), difficulty staying asleep (38%), and drowsiness (38%).

For citalopram, in the 12-week study by King et al.[79] (n = 73 citalopram, 76 placebo; mean age ~9 years), 97.3% of subjects with ASD treated with citalopram experienced at least one treatment emergent adverse event. They were significantly more likely to experience adverse events compared to those treated with placebo, specifically: increased energy level (38%), impulsiveness (19%), decreased concentration (12%), hyperactivity (12%), stereotypy (11%), diarrhea (26%), insomnia (23.3%), and dry skin or pruritus (12%).

In contrast, in RCTs of citalopram for the treatment of depression in children and adolescents with typical development, the most commonly reported adverse events were headache, gastrointestinal issues, and insomnia.[92] Specifically in the 8-week RCT by Wagner et al.[93] of citalopram for typically developing children with depression (n = 89 citalopram, 85 placebo; mean age, 12 years), rhinitis (14%), nausea (14%), and abdominal pain (11%) were the only adverse events reported in >10% of subjects taking citalopram, and in the 12-week RCT by von Knorring et al.[94] of citalopram for typically developing adolescents with depression (n = 124 citalopram, 120 placebo; mean age, 16 years), headache (26% and 25%), nausea (19% and 15%), and insomnia (13% and 11%) were the most common in both groups (citalopram and placebo, respectively), with only fatigue being the adverse event reported significantly more often in the citalopram group (6%) than the placebo group (1%).

Dosing

Children with PDD typically require smaller doses of SSRIs compared to children with typical development and may experience adverse emotional/behavioral events at higher doses. For fluoxetine, the mean final daily dose of fluoxetine in Hollander et al.'s study[78] of children with PDD was 9.9 mg, or 0.36 mg/kg. This is compared to Geller et al.[90] and Liebowitz et al.'s[91] studies of typically developing children with OCD, in which mean final daily fluoxetine dose was 24.6 and 64.8 mg (after the acute phase), respectively. Additionally, in RCTs of typically developing children with depression and other forms of anxiety, fluoxetine was well tolerated at mean daily doses of 20 mg,[95–97] 28.4 mg and 33.3 mg,[98] and 40 mg.[99]

For citalopram, the mean daily dose in the King et al. study[79] of children with ASD and repetitive behavior was 16.5 mg. In studies of citalopram use in typically developing children and adolescents with depression, citalopram was tolerated at mean daily doses of 24[93] and 26 mg.[94]

The issue of individuals with PDD requiring lower dosages of SSRI might diminish in adulthood, because RCTs of SSRIs in adults with ASD demonstrate mean daily doses close to that expected for typically developing adults: fluoxetine—36.7[101] and 64.8 mg[101]; fluvoxamine 276.7 mg.[76]

CASE 88-3

QUESTION 1: N.W. is a 6-year-old girl with a history of supraventricular tachycardia (SVT) at birth, well controlled on propranolol since infancy. N.W. also has a diagnosis of ASD. Over the past year, she has been trialed on varying stimulant formulations and doses for the treatment of ADHD symptoms. However, N.W.'s mom reports only small improvement, but significant worsening of repetitive behavior and aggression. N.W. has been pushing, hitting, and throwing things at school and home. Additionally, N.W. has had a decrease in appetite and lost ~4 lb. At home, N.W. has recently developed a lot of anxiety, refusing to go to school and participate in outdoor activities. Her mother notes that N.W. appears to be isolating herself more and not enjoying activities that used to make her happy. The prescriber discontinues methylphenidate and starts N.W. on risperidone 1 mg/day for aggression and repetitive behaviors. She also starts her on fluoxetine 10 mg/day for depression and anxiety.

You get a call from N.W.'s mother 3 days after N.W. starts the new medication regimen. N.W.'s mother reports that N.W. is extremely lethargic, and seems confused. She fell the last few times she tried to get out of bed. You have the mother use a blood pressure cuff she has at home to measure N.W.'s vital signs. Based on the results, N.W. is bradycardic and hypotensive. What is your recommendation?

The dose of risperidone that N.W. was started on is high. Additionally, you know that fluoxetine is a strong 2D6 inhibitor, although risperidone and propranolol are 2D6 substrates. Therefore, fluoxetine may be decreasing the clearance of both the risperidone and propranolol. You decide to call the provider and discuss the interaction and adverse effects that N.W. is experiencing.

CASE 88-3, QUESTION 2: The prescriber is thankful for the call and asks for your advice on altering the current regimen. What changes would you recommend?

You recommend discontinuation of the fluoxetine and initiation of sertraline 12.5 mg/day, because sertraline is a weaker inhibitor of 2D6. You would recommend the continuation of risperidone at a reduced dose of 0.5 mg/day.

Target Symptoms

Most studies looking at symptoms of anxiety and depression in children with ASD have used rating scales validated in typically developing children. For anxiety, predictors that children with ASD will manifest a high level of parent-reported anxiety include the following: IQ > 70,[102–104] higher levels of parent-rated social impairment,[102,103] and increased age[103]; additionally, it seems that children with IQ < 70 might experience higher levels of parent-reported anxiety if they demonstrate more adaptive social behaviors.[102,103] For depression, higher IQ and age seem correlated with higher depression ratings[105] and both seem to predict lower self-perceived social competence in children with ASD.[106] Lower self-perceived social competence, in turn, seems to predict high levels of depression symptomatology.[106] Additionally, it seems that adults with ASD with less social impairment (higher social functioning) were more likely to be categorized as depressed.[107] All of this seems to indicate that the more individuals with ASD are aware of social impairments, or exposed to social interactions, the more likely they are to demonstrate classically recognizable symptoms of anxiety or depression.

However, this body of literature, due to the scales that are used, only addresses anxiety and depressive mood symptoms that are also seen in typically developing individuals. Clinicians who work with individuals with PDD are well aware that anxiety and depression might manifest in alternative ways in this population. Individuals with ASD often have impaired abilities to communicate their emotional experiences to others and can have significant trouble managing their emotions. This routinely leads to alternative manifestations of emotions like anxiety and depression, in the forms of rigidity, tantrums, oppositionality, social avoidance, hyperactivity, repetitive behaviors, irritability, aggression, and self-injury. As mentioned above, studies of SSRIs to target some of these behaviors, have been mixed.

Overall though, it seems that case studies and open-label trials have shown possible benefits for the use of SSRIs in children with PDD for the treatment of classically recognized symptoms of anxiety and depression. To avoid significant emotional and behavioral adverse events though, target dosing should be lower than in children with typical development.

SLEEP

Melatonin

The medication with the strongest research backing for the treatment of sleep disturbance in individuals with developmental disabilities is melatonin. Hollway and Aman's excellent review[108] found thirteen RCTs of individuals with sleep disturbance, many of which also with developmental disabilities. All thirteen RCTs had positive findings, particularly for sleep initiation and sleep maintenance, with the longest trial being 10 weeks in duration. The effect sizes for sleep onset latency ranged from .25 to 1.63, and for total sleep time from .25 to 1.0. Adverse effects were generally mild and similar to placebo. Doses ranged from 2.5 to 10 mg.

Ramelteon

The MT_1/MT_2 melatonin receptor agonist has limited evidence in children with developmental disabilities, though considerable positive findings in adults with typical development, specifically in primary insomnia and sleep maintenance.[108] Adverse effects were mild and similar to placebo, and doses ranged from 4 to 64 mg.

Clonidine

Although no RCTs have been conducted in children with developmental disabilities and sleep disturbance, retrospective reviews have shown benefits in helping with sleep disturbance, with doses ranging from 0.05 to 0.1 mg.[108]

Trazodone

Although no RCTs have been conducted in children with sleep disorders, four open-label studies in children and two in adults showed benefits for improving sleep, including sleep architecture.[108] Doses ranged from 25 to 150 mg.

Mirtazapine

One open-label study in children and one RCT in adults showed benefits for the treatment of sleep problems, with mild adverse effects, which included increased appetite, irritability, and sedation.[108] Doses ranged from 7.5 to 45 mg.

Diphenhydramine

Despite its abundant use in pediatric patients for sleep disturbance, only three RCTs were identified by Hollway and Aman for its use in pediatric subjects.[108] Two of the studies were negative, one showed benefit, and none of them were specifically in children with developmental disabilities.

Zolpidem

Studies are limited, and none seem to have studied individuals with developmental disabilities, though benefits seem greater in adolescents and adults, and less effective in children.[108]

Benzodiazepines

In partially or uncontrolled studies in children, and controlled studies in adults, it seems that benzodiazepines may be most effective at helping sleep disturbances associated with parasomnias (e.g., periodic limb movement disorder, tongue biting, REM sleep behavior disorder) though with considerable risks of adverse effects, including tolerance, dependence, rebound insomnia, daytime sedation, and cognitive impairment.[108]

Overall, it seems that melatonin is the most well-studied, effective, and safe medication option for treating sleep disturbance in individuals with developmental disabilities. Although promising evidence for ramelteon, trazodone, mirtazapine, and clonidine exists, further research is needed in individuals with developmental disabilities. Research evidence does not seem to support the wide use of diphenhydramine for sleep disorders in children, and although zolpidem and benzodiazepines may be of benefit for sleep in some, they should be used with caution, and primarily in adults for zolpidem, and those with parasomnias for benzodiazepines.

CASE 88-4

QUESTION 1: T.T. is a 10-year-old boy with ASD and significant sleep disturbances. His father has tried diphenhydramine for the last few weeks but has not seen any meaningful improvement in T.T.'s total sleep time. Last year, T.T. had a trial of melatonin 2.5 mg daily with only a small recognized improvement. T.T.'s clinician is thinking about starting a low-dose benzodiazepine, however, is weighing the concerns for adverse effects. T.T.'s clinician asks for your opinion.

You note that the dose of melatonin last year may have been on the lower range and you would recommend another trial of melatonin before considering a controlled substance. The dose you would recommend is 5 mg taken approximately 1 hour to T.T.'s bedtime. You note that this dose can be increased to 10 mg if an adequate response is not seen.

Table 88-2

Summary of Target Symptoms and Pharmacologic Treatment

Target Symptom	Treatment Medications/Classes to Consider
Hyperactivity	Stimulants, atomoxetine, α_2 agonists
Irritability/aggression	Risperidone, aripiprazole
Repetitive behaviors	Risperidone, aripiprazole, fluoxetine, clomipramine, fluvoxamine,
Self-injurious behavior	Risperidone, clomipramine, naltrexone
Anxiety/depression	SSRIs
Sleep	Melatonin, ramelteon, clonidine, trazodone, mirtazapine, zolpidem, benzodiazepines

SSRI, selective serotonin reuptake inhibitors.

Attention Deficit Hyperactivity Disorder in Children, Adolescents, and Adults

Michael C. Angelini and Joel Goldstein

CORE PRINCIPLES

		CHAPTER CASES
1	Attention deficit hyperactivity disorder (ADHD) is a heterogeneous psychiatric disorder that consists of multiple subtypes, including inattention, hyperactivity/impulsivity, and a combination of these two types. For diagnostic criteria to be met, there must be evidence that these symptoms are present in multiple settings and that the individual exhibited this psychopathology before the age of 12 years. These symptoms cannot be because of other illnesses.	**Case 89-1 (Question 1), Table 89-1**
2	Behavioral therapy is an important component of any effective treatment plan and typically includes educational interventions, creation of a structured environment for the child, and introducing contingency training.	**Case 89-1 (Questions 1-3)**
3	Stimulant medications are highly effective for the rapid relief of ADHD symptoms and substantially improve a child's prognosis. Individuals who fail to respond adequately to one type of stimulant will often do well with another, suggesting that subtle differences exist in the pharmacologic mode of action. Although the duration of pharmacologic action is relatively brief for stimulants, a variety of preparations have been approved that can prolong the relief of ADHD symptoms and permit once-daily dosing.	**Case 89-1 (Questions 3-5), Table 89-2**
4	There are a number of non-stimulant medications that have proven to be effective for ADHD over the years, including atomoxetine a NE reuptake inhibitor, and α-agonists. These medications may be viable options for the management of treatment-resistant illness as well as in patients with a history of substance abuse. They also possess a different side effect profile than stimulants and have a delay until therapeutic effects are evident.	**Case 89-1 (Question 6), Table 89-2**
5	Many people are reluctant to consider stimulant medications for ADHD treatment because of unfounded fears about drug tolerability and abuse. As a result, there have been a wide variety of alternative treatments considered for use, including changes in dietary habits, ingestion of herbs and supplements, and other somatic interventions. At the present time, the evidence supporting these options is sparse, although the rigor of investigations has steadily improved in recent years, and there is hope that some of these options may prove to be beneficial.	**Case 89-2 (Question 1)**

⑥ ADHD is commonly associated with several psychiatric and medical comorbidities, and these concurrent conditions often influence treatment plans. Tic disorders such as Tourette syndrome are frequently found in children with ADHD, but research evidence suggests that stimulants are not only safe but also effective in this particular population.	**Case 89-1 (Question 1)**
⑦ Some children with ADHD will continue to have symptoms of their illness well into their adult years, usually of the inattention subtype. There is a growing awareness that adults with ADHD have significant social and occupational impairments. Fortunately, medications used to treat ADHD in children appear to be equally effective in adults. Stimulants are the most effective agents but have the unique side effect risk of abuse and diversion. Monitoring for this is essential. If abuse or diversion occurs then a reevaluation of the diagnosis is necessary as well as a change to a medication with less risk of misuse.	**Case 89-2 (Question 2)**

Although the diagnosis and treatment of attention deficit and hyperactivity disorder (ADHD) have been associated with considerable controversy, ADHD is a serious psychiatric condition that has been well described in the medical literature for more than two centuries.[1] There are highly effective pharmacologic treatments that ameliorate the core symptoms of the illness. These agents are generally safe and have been shown to improve long-term prognosis.[2]

By definition, ADHD symptoms manifest in childhood and will often persist into adulthood in many cases. If left untreated, ADHD can produce significant impairments in academic performance and social functioning; adults with ADHD are often hindered in occupational settings as well.[3] Psychiatric comorbidities are commonly encountered among individuals suffering from ADHD, including developmental disorders, mood disorders, and substance abuse.

Although hyperactivity had been recognized as a troublesome childhood behavior for many years, ADHD was not formally described in the Diagnostic and Statistical Manual of Mental Disorders until the third edition was released in 1980. The recently released DSM-5 describes three different subtypes of ADHD including “Predominantly inattentive presentation,” “Predominantly hyperactive/impulsive presentation,” and “Combined presentation.”[4] The DSM-5 also requires the diagnosis by age 12, in contrast to DSM IV that required the onset of impairment before age 7. Qualitatively the core symptoms of ADHD will differ according to gender, with boys more likely to exhibit the hyperactive/impulsive subtype (vs. girls).[5] These symptoms often change with time as hyperactive and impulsive behaviors recede during adolescence, and inattention predominates among adolescents and adults with ADHD.[6]

Although the effectiveness of pharmacologic treatments for ADHD has been widely replicated, many children and adolescents with ADHD will receive suboptimal treatment for a variety of reasons, including parental reluctance to consider psychotropic medications, the perceived stigma of mental illness, and well-described deficiencies in the delivery of health care to persons with psychiatric conditions.[7] It is important to note that ADHD poses a huge economic burden to Western society. A meta-analysis by Doshi et al. reports overall national incremental costs of $143 to $266 billion in the United States.[8] The economic impact related to adults with the disorder from productivity and income loss is greatest, although there are also significant costs associated with youth with the disorder from educational and health expenses. Further, the study documents significant "spillover costs" for family members of individuals with ADHD.[8]

Stimulants such as methylphenidate and amphetamine have been the mainstay of ADHD treatment in children for more than 30 years, and recent studies have demonstrated acute and long-term benefits in adolescents as well as adults.[1,9-11] Unfortunately, stimulants have not been consistently shown to decrease delinquency rates. They have also been implicated with rare but serious side effects, and they carry an elevated risk of diversion and abuse.[11–13] Pharmacologic alternatives to stimulants have been identified in recent years and have proven to be useful, albeit often as second-line agents among individuals who have significant side effects and those with medical or psychiatric comorbidities.[11] The benefits of cognitive behavioral psychotherapy have also been emphasized in recent years, and most experts now contend that the combination of pharmacotherapy with family-based cognitive behavioral interventions will generate the best long-term prognosis for individuals with this disorder.[2]

Recent landmark studies have helped clarify important aspects of diagnosis and treatment with regard to ADHD. The Multimodal Treatment of Attention Deficit Hyperactivity Disorder Study (MTA) is considered a groundbreaking study of ADHD treatments and outcomes. The main findings were released in 1999, but additional findings have been subsequently released. MTA was a multisite study that differed from earlier studies of ADHD in that the duration of the study was significantly longer (up to 14 months) and that the study compared the use of both medication and cognitive behavior therapy, both alone and in combination with routine community-based treatment. The central findings of MTA included the following: (1) Medication alone and in combination with CBT was more effective than intensive behavioral treatment alone or routine community-based care, (2) youth receiving combined treatment required lower doses of medication, and (3) youth with associated mental health issues, in addition to ADHD, had better outcomes with combined treatment than with medication alone.[14,15]

The question of medication treatment for preschool children presenting with ADHD symptoms is a controversial issue. The "Preschool ADHD Treatment Study" (PATS) is considered a landmark study in this arena. The majority of the findings were released in 2006. The central findings include (1) preschool children tend to respond better and with fewer adverse effects with lower doses of medication and

(2) preschool children are more sensitive to the adverse effects of psychostimulants and require closer monitoring. In particular, younger children tend to have more emotional adverse effects such as irritability and a tendency toward crying.[16,17]

EPIDEMIOLOGY

ADHD is a chronic neurobehavioral disorder, with an overall estimated prevalence of 6% to 12% in school-aged children worldwide.[18] The Centers for Disease Control and Prevention analyzed data from the 2006 National Survey of Children’s Health and reported that the incidence of ADHD diagnoses has risen annually by an average of 3% between 1997 and 2006.[19] In 2006, 7.4% of US children aged 4 to 17 years were diagnosed with ADHD. The DSM-5 reports that “ADHD occurs in most cultures in about 5% of children and about 2.5% of adults.” The diagnosis is more common in males with a ratio of 2:1 in children and 1.6:1 in adults.[4] It is hypothesized, however, that this gender predominance may be exaggerated because the more overt hyperactive subtype is more common in boys and the less overt inattentive subtype is more common in girls. As ADHD transitions into adulthood, the prevalence falls to 4.4% (standard error 0.6), with a higher risk found in previously married men who are unemployed and non-Hispanic white.[19]

PATHOPHYSIOLOGY

Various abnormal genetic and neurochemical abnormalities are associated with ADHD. Estimates of heritability of ADHD range in the area of 0.7, indicating that ADHD is one of the most heritable conditions in psychiatry.[20] Family studies have demonstrated that the relative risk of ADHD is 6 to 8 times higher among first-degree relatives of persons with ADHD compared with the general ADHD population.[21] Several candidate genes associated with ADHD have been identified, such as the dopamine receptor, dopamine-transporter receptor, and serotonin transporter gene.[22,23] Despite a small causal effect, no single gene is responsible for the symptoms seen with ADHD, but rather these symptoms are likely the result of interactions among several genes, which influence multiple neurotransmitters, including serotonin, dopamine, and norepinephrine.[22]

Multiple neuroimaging studies have documented consistent abnormalities in brain structure and development with youth and adults with ADHD. Subjects with ADHD have been shown to have reductions in global brain volume.[24] Specifically, the reduction in volume is most prominent in the prefrontal cortex, basal ganglia, cerebellum, and parieto-temporal regions.[24] Functional magnetic resonance imaging studies have also shown hypoperfusion with memory tests in the anterior cingulate areas in ADHD patients.[25] This area of the brain is responsible for behavioral and functional abilities that may manifest in patients with ADHD as difficulties in organization, mood, motivation, self-regulation, and ability to retain specific information while performing a particular task, which are abilities referred to as executive functioning. These findings are research population–based findings. These studies are not yet useful in clinical practice for accurate diagnosis.

Etiology

ADHD is a heterogeneous behavioral disorder with a variety of theorized etiologies. Clearly, the research suggests a strong genetic component. However, to this point, no specific genetic risk factor has been identified.[20] As a result, other environmental and congenital etiologies have been considered and studied. Examples of studied etiologies for ADHD include maternal smoking, dietary factors, prematurity/low birth weight, and family environment/parenting behavior. Of these proposed factors, low birth rate is the factor with the most confirming research evidence.[20,26] The potential impact of parenting behavior, in particular, is a complex question as youth with ADHD often present more significant challenges to parents. Further, as ADHD is highly heritable, many parents of youth with ADHD may have ADHD themselves.

DIAGNOSIS, SIGNS, AND SYMPTOMS

The diagnosis of ADHD is a clinical diagnosis that may be supported by various types of screening tools and neuropsychologic assessment. The diagnosis of ADHD in a child is based upon the DSM-5 criteria (Table 89-1). The evaluation should include clinical interviews with the patient and/or parent, physical examination (including neurologic status), obtaining history regarding functional pattern in school or daycare setting, evaluation for comorbid psychiatric disorders, and review of the patient's medical, social and family histories.[2] Other sources of valuable information include performance reports (e.g., report cards or job reviews) and ADHD rating scales scored in two different settings.[4] There are a number of validated rating scales available both proprietarily and in the public domain. Some of the rating scales have different versions for parents and teachers. Rating scales are helpful both for diagnosis and for monitoring treatment outcome.

The recent publication of DSM-5 included a number of revisions to the diagnostic criteria for ADHD. To meet criteria for ADHD, the child must have six or more symptoms present in two different settings (e.g., home, school, etc.) for a minimum of 6 months. Furthermore, there must be evidence that these symptoms were present before the age of 12 years. Based on these criteria, three types of ADHD are identified: predominantly inattentive, predominately hyperactive/impulsive, and combined. The diagnostic criteria require that the symptoms interfere with or impact functioning in daily life so that care providers will look for symptoms that have a negative impact on the child's education, relationships, or social life (see Table 89-1). On occasion, however, parents or teachers may "pressure" clinicians into writing psychostimulant prescriptions for a "let's see if it helps" trial. If the medication is helpful, they may assume incorrectly that the diagnosis of ADHD is validated. Additionally, DSM-5 eliminated the exclusion criteria for Autism Spectrum Disorder. However, the DSM-5 mandates that the symptoms of ADHD "do not occur exclusively during the course" of another psychiatric disorder.[4]

Table 89-1

Diagnostic Criteria for Attention Deficit Hyperactivity Disorder

Inattention Factor
(Six or more of the following nine behaviors need to be present for ≥6 months in two or more settings, such as home, school, or physician's office.)
1. Careless mistakes or inattention to detail 2. Reduced attention span 3. Poor listener 4. Cannot follow instructions and does not complete tasks 5. Difficulty organizing tasks and activities 6. Avoids and/or dislikes chores or homework 7. Loses things needed for tasks and activities 8. Easily distracted by extraneous stimuli 9. Forgetful in daily activities
Hyperactivity/Impulsivity Factor
(Six or more of the following nine behaviors need to be present for ≥6 months in two or more settings, such as home, school, or physician's office.)
Hyperactivity 1. Fidgets with hands/feet or squirms in chair 2. Cannot remain seated in the classroom 3. Uncontrollable/inappropriate restlessness 4. Difficulty in engaging in play or leisure activities quietly 5. Often on the go and appearing driven by a motor 6. Excessive talking Impulsivity 7. Blurts out answer prior to completion of question 8. Difficulty waiting turn 9. Interrupts or intrudes on others

Reprinted with permission from American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders. 4th ed. Text Revision (DSM-5). Arlington, VA: American Psychiatric Association Press; 2015.

Establishing a diagnosis of ADHD in an adult who has never been treated for the disorder during childhood is difficult. In adults, ADHD is a clinical diagnosis that relies on their recollection of ADHD symptoms as a child to which DSM-5 criteria validated for children are applied. Unlike teachers who are ordinarily familiar with the symptoms associated with ADHD in children, spouses, coworkers, and employers are often unfamiliar with ADHD as a disorder that can also affect adults. They may attribute the individual's difficulties to being lazy or to underachievement.

COMORBIDITY AND PROGNOSIS

Between the ages of 10 and 25 years, the signs and symptoms of ADHD decrease in frequency and severity by about 50% every 5 years but will generally persist into adulthood.[6] In the differential diagnosis of ADHD, it is critically important to distinguish ADHD from various behavioral, developmental, or medical conditions. Psychiatric comorbidity is more common with ADHD as up to 87% of children will be diagnosed with at least one additional psychiatric disorder and 67% have at least two or more disorders.[27]

Other psychiatric conditions that frequently coexist or imitate symptoms of ADHD include conduct disorder, oppositional defiant disorder, Tourette syndrome, depression, anxiety disorders, and obsessive–compulsive disorder. Of these conditions, anxiety disorders and mood disorders are most commonly misdiagnosed as ADHD. The comorbidity of ADHD and learning disabilities is both complex and often leads to significant academic challenges. Studies suggest that 25% to 35% of youth with ADHD will also have language-based or other learning disabilities.[27] Clinical wisdom suggests that ADHD often presents early in the child's academic career (e.g., kindergarten or first grade), whereas learning disabilities may present later in the elementary years, when children are "reading to learn" rather than "learning to read." Medication is a central treatment component for ADHD, whereas learning support and specialized teaching strategies are the interventions of choice for youth with learning disabilities. Medications are not helpful for the treatment of learning disabilities.

It has been known for decades that family histories from first-degree relatives of probands with ADHD reveal increased rates of ADHD (25% concordance rate), polysubstance dependence, antisocial personality disorder, depression, and anxiety disorders.[28] Children with ADHD are at an increased risk of having antisocial behavior, depression, and substance abuse problems as adults. ADHD symptoms persist into adulthood in the majority of these comorbid patients.[11] Adults with

ADHD are usually self-sufficient, but they have poorer academic performance, poorer job performance, and lower socioeconomic status than do their siblings. They also have more frequent divorces, job changes, and car accidents. Most adults with ADHD report a high level of subjective distress (79%) and interpersonal problems (75%).[29]

Medical conditions often complicate the diagnosis of ADHD and should be excluded before initiating treatment. These medical conditions include head injuries, seizure disorders, metabolic disorders, cerebral infection, toxic exposures (e.g., chronic lead exposure), sleep problems, substance abuse, and hyperthyroidism.

CASE 89-1

QUESTION 1: M.T. is a 12-year-old girl who recently started middle school. M.T.'s mother calls the pediatrician looking for advice. M.T. was adopted at 2 months of age from Guatemala and little is known about prenatal care or her life before the adoption. M.T. is having a good deal of difficulty with the transition to middle school. She seems overwhelmed with the amount of work and has become withdrawn and angry. The guidance counselor has called the parents because M.T. has missed most of her homework assignments. M.T.'s mother feels at a loss because M.T. now has many more teachers and they don't seem to know her or to support her in the same way as the teachers in the elementary school. M.T. has begun counseling with a social worker in the community but does not want to go. Her mother is interested to know if medication may be of help. How do you think about the differential diagnosis?

Depression is the most prominent diagnosis that comes to mind. However, it is important to remember that comorbidity is quite common in youth with psychiatric disorders. It is important to consider if there are underlying, less obvious disorders or circumstances that may be contributing.

CASE 89-1, QUESTION 2: What are the next steps in the evaluation?

The pediatrician refers M.T. to a child/adolescent psychiatrist for evaluation. The professionals help the parents request an educational assessment through the school. The latter includes both an academic and psychologic assessments. The assessments suggest underlying poor self-esteem. However, there is also evidence of slow processing speed and other evidence of ADHD and executive functioning deficits. The Vanderbilt rating scales confirm the diagnosis of ADHD.

There are a number of validated instruments to assist with the diagnosis and clinical management of ADHD. Often, these instruments have a parent and teacher version. Commonly used instruments include the Conners Global Index, the SNAP IV, DuPaul Rating Scale for ADHD, and the Vanderbilt Rating Scale. Some rating scales are proprietary and others such as the Vanderbilt is in the public domain.[30]

CASE 89-1, QUESTION 3: What are the first-line interventions?

The psychiatrist provides psychoeducation to M.T. and her parents about ADHD. They discuss that ADHD may be missed more commonly in girls, and that youth with ADHD often develop concurrent depression, anxiety, conduct disorders, and substance-use disorders because their experience in school and activities often leads to feelings of inadequacy. Additionally, an Individualized Educational Plan (IEP) is developed for M.T. to provide more supports in the school setting. Special accommodations such as added time for exams, a seat in the front of the class, and the availability of fidget toys are specified in the IEP.

M.T. continues in counseling with the social worker, in which they focus on cognitive and behavioral strategies to manage both her ADHD symptoms and her depression and poor self-esteem. All agree that it is prudent to hold off on any medication for depression to see if the other interventions are effective in alleviating the symptoms of depression.

The ADHD symptoms are tracked with Vanderbilt rating scales completed by parents and teachers. Medication treatments for ADHD are discussed. With informed consent, a trial of a psychostimulant is begun.

TREATMENT

Optimal strategies to manage ADHD symptoms that are moderate to severe in nature should focus on the combined use of behavioral and pharmacotherapy interventions. It is important to recognize that ADHD is a chronic disorder with symptoms that frequently continue into adolescence and adulthood. Before developing a treatment plan, defined and realistic treatment goals should be established collaboratively with the child, parent, and school.

Several ADHD consensus statements, practice parameters, and guidelines have been developed, based on both evidence-based literature evaluation and expert opinions, to assist clinicians in evaluating, diagnosing, and managing patients with ADHD in a consistent manner.[2,31–34]

Behavioral Therapy

During the years, numerous psychosocial or educational programs have been studied for their potential benefit in controlling ADHD symptoms and maximizing function.[2] Behavioral interventions have been among the most popular nonpharmacologic approaches, with programs emphasizing the creation of a structured environment containing minimal distractions both at home and in school. Contingency training is another common component of behavioral therapy for ADHD, with children receiving tokens for specific tasks or achievements, as well as punishments (e.g., revoking privileges) for maladaptive behaviors. Although most treatment guidelines continue to advocate trying some type of structured behavioral modification, the empiric evidence that such programs improve functioning or prognosis is certainly not as strong as it is for pharmacotherapy.[33]

The previously mentioned Multimodal Treatment Study of Children with ADHD was a landmark study in reviewing the relative impact of medication and nonpharmacologic treatment.[14] The MTA Cooperative Group study, as it is commonly known, was designed to compare long-term medication and behavioral treatments with respect to efficacy and acceptability. A group of 579 children between 7 and 10 years of age with the combined type of ADHD were recruited and randomly assigned to four different treatment groups: medication management, behavioral treatment, medication plus behavioral treatment, or typical community treatment. Behavioral interventions were delivered in a group-based recreational setting and included an 8-week, 5-days/week, 9-hours/day, intensive program administered by a counselor or aide. Once school started, the subjects in this arm of the study received 60 school days of a part-time, behaviorally trained, paraprofessional aide who worked directly with the child. In addition, the child's teacher received 10 to 16 sessions of biweekly consultation that focused on classroom behavior management strategies. Daily behavior report cards were sent home to parents. At the same time, families were involved in 27 group therapy meetings plus 8 individual family meetings. Of the children receiving medication, 75% received methylphenidate, 10% received dextroamphetamine, and 15% received pemoline, imipramine, clonidine, guanfacine, or bupropion. After the 14-month study, it was concluded that drug treatment was more effective than behavioral treatment according to parents' and teachers' ratings of inattention, and teachers' ratings of hyperactivity/impulsivity. Combined treatment (drug treatment plus behavioral modification) was preferred by parents, but the therapeutic advantage versus medication did not achieve statistical significance. Combined treatment was significantly more effective than behavioral treatment and community care for reducing ADHD symptoms, according to both parent and teacher reports, but a subgroup analysis of children with comorbid conditions (e.g., conduct, oppositional defiant, anxiety, or affective disorders) found behavior management to be as effective as monotherapy. A 3-year follow-up study revealed that all four interventions were equally effective in improving academic performance and social functioning with time, but given the costly and labor-intensive nature of the behavioral modification, in particular pharmacotherapy, it continues to be regarded as the first-line treatment for children with at least moderate ADHD symptoms.[15] There have been a variety of school-based, clinic-based, and home-based interventions to address ADHD symptoms, mainly with positive results. Additionally, specialized summer treatment programs have been established to provide more intensive intervention when school is not in session.[35]

Pharmacotherapy

STIMULANTS

Stimulants are considered the most effective option to treat ADHD, with more than 60 years of clinical experience accrued. Currently there are two basic types of stimulants marketed in the United States, methylphenidate based and amphetamine based, and they have all been reported to improve academic performance and behavior in children with ADHD (Table 89-2).[32]

Table 89-2

Overview of Common Drugs to Treat Attention Deficit Hyperactivity Disorder

Drug		Duration of Action	Pediatric Dose	Adult Dose	
Stimulants					
Methylphenidate C-II	Aptenso XR Concerta (generic) Metadate CD Metadate ER Methylin ER Quillichew ER Quillivant XR Ritalin IR Ritalin SR Ritalin LA Daytrana Transdermal Patch	Long Long Long Intermediate Intermediate Long Long Short Intermediate Long Long	20–60 mg a day 18–72 mg a day 20–60 mg a day 20–60 mg a day 20–60 mg a day 20–60 mg a day 20–60 mg a day 20–60 mg a day 20–60 mg a day 20–60 mg a day 10–30 mg per 9 hour patch	20–60 mg a day 18–72 mg a day 20–60 mg a day 20–60 mg a day 20–60 mg a day 20–60 mg a day 20–60 mg a day 20–60 mg a day 20–60 mg a day 20–60 mg a day 10–30 mg per 9 hour patch	Adult doses may need to be higher and can be titrated up based on tolerability
Dexmethylphenidate C-II	Focalin Focalin XR	Short Long	5–20 mg a day 5–20 mg a day	20 mg a day 20 mg a day	
Amphetamine C-II	Adzenys XR ODT Dynanavel XR Evekeo	Long Long Long	6.3–18.8 mg a day 20 mg a day 2.5–40 mg a day	No approved max. dose No approved max dose No	Adult doses likely to be similar to pediatric doses and titrated as tolerated

				approved max. dose	
Amphetamine/Dextroamphetamine C-II	Adderall Adderall XR	Short Long	10–40 mg a day 10–30 mg a day	10–40 mg a day 10–20 mg	Doses may be increased as tolerated
Dextroamphetamine C-II	Dexedrine Dexedrine XR ProCentra Zenzedi	Short Long Short Short	5–40 mg a day 5–40 mg a day 5–40 mg a day 5–40 mg a day	5–40 mg a day 5–40 mg a day 5–40 mg a day 5–40 mg a day	
Lisdexamfetamine C-II	Vyvanse	Long	30–70 mg a day	30–70 mg a day	
Methamphetamine	Desoxyn	Long	5–25 mg a day	No approved dose	Strongly recommended not to use this product
Non-stimulants					
Noradrenergic Reuptake Inhibitor					
Atomoxetine	Strattera	Long	40–100 mg a day	40–100 mg a day	
α-2 Receptor Agonist					
Clonidine Guanfacine	Clonidine Kapvay Guanfacine Intuniv	Short Long Short Long	0.1–0.3 mg a day 0.1–0.4 mg a day 1–4 mg a day 1–4 mg a day	0.1–0.3 mg a day 0.1–0.4 mg a day 1–4 mg a day 1–4 mg a day	Use in adults not well studied. Higher doses have been used for control of BP. Monitoring for hypotension is recommended

BP, blood pressure; IR, immediate release; SR, sustained release; ER and XR, extended release; ODT, orally disintegrating tablet; CD, controlled delivery.

A review of short-term clinical trials that evaluated the safety and efficacy of stimulants in nearly 6,000 children and adults with ADHD showed a 75% to 80% improvement in patients treated with stimulants compared with 5% to 30% treated with placebo.[36] Although stimulant drugs are grouped as a class based on their pharmacologic effect of increasing dopamine and norepinephrine levels in the synapse, the mechanisms by which stimulant drugs exert this effect varies slightly. These subtle differences in the mechanism of action support the possibility that patients who respond partially to one stimulant may respond completely to another. In fact, approximately 20% to 25% of those who respond poorly to one medication will respond positively to another and up to 90% of children will respond if both are tried.[37] Stimulants also are rapid acting and have predictable effects, with response typically within 2 hours.[38]

Methylphenidate and dexmethylphenidate block the reuptake of dopamine from the synaptic cleft into the presynaptic neuron via the dopamine transporter protein. Methylphenidate is metabolized into ritalinic acid via carboxylesterase CES1A1, a non CYP450 enzymatic pathway.[39,40]

The most common side effects of methylphenidate include appetite suppression, insomnia, headache, nausea and vomiting, and abdominal pain.[40]

A long-acting methylphenidate transdermal formulation is available. As with any transdermal system, drug delivery can vary greatly because of heat and site-related skin porosity differences. AUC and Cmax can increase 300% if the patch is applied to an inflamed area and 250% if the patch area is exposed to heat such as going outside and exercising in the sun.[2,41–43] The patch is applied to the hip area for 9 hours, and methylphenidate is steadily released and absorbed into the circulation for about 11.5 hours. When compared to the oral long-acting Oros release system, methylphenidate’s side effects were similar between the two products but numerically higher in the transdermal arm compared to the oral arm. One side effect exclusive to the patch is skin irritation which can occur from 3% to 40%.[41]

Amphetamines, including mixed amphetamine salts, dextroamphetamine, and lisdexamfetamine, enhance the release of both dopamine and norepinephrine from storage vesicles in the presynaptic neuron and block their storage in addition to blocking their reuptake from the synaptic cleft. They also have a weak MAOI effect.[44,45]

Dextroamphetamine is metabolized via CYP2D6. A strong inhibitor of 2D6 could increase levels twofold. The long-acting prodrug lisdexamfetamine requires enzymatic hydrolysis in the blood to cleave off the L-lysine portion of the molecule. This leaves just dexamphetamine available for activity.[46,47] Lisdexamfetamine is rapidly absorbed, but the step of hydrolysis results in a delayed release of dextroamphetamine in the circulation allowing for once a day dosing.

Since approximately two-thirds of children and adolescents with ADHD respond equally to methylphenidate or amphetamine products, the preferred agent should be based on duration of action, formulation preferences, and cost.[33] As shown in Table 89-2, stimulant preparations are classified based on duration (i.e., immediate [2–5 hours], intermediate [6–8 hours], and long-acting [10–12 hours]) and available delivery systems. Long-acting formulations are preferable to intermediate and short acting, because it provides uninterrupted benefit allowing the child to avoid going to the school nurse for doses or lack of effect between doses.[48] Many long-acting options are biphasic, which provides an immediate-release (IR) dose then a second long-acting dose a few hours later. For example, Ritalin LA, Metadate CD, Focalin XR, and Adderall XR all contain both immediate and enteric-coated, delayed-release beads that mimic the blood concentrations seen with immediate-release stimulant preparations given twice daily. Although a prescription methamphetamine product does have FDA approval for treatment of ADHD, no expert guidelines recommend it because of high-abuse liability and neurotoxicity.

Adverse Effects

Both types of stimulants are similar in their side effect profiles. Adverse drug reactions such as insomnia and appetite loss are mild, and tolerance often develops within a few days. These reactions can be easily managed by adjustment in dose and timing if necessary (Table 89-3). In a double-blind, crossover study comparing side effects of methylphenidate and dextroamphetamine, surveyed parents reported worsening appetite (vs. baseline) with methylphenidate; severe insomnia and appetite suppression were reported with dextroamphetamine.[49] Side effects that were significantly more severe with methylphenidate (vs. dextroamphetamine) included insomnia, appetite suppression, irritability, proneness to crying, anxiety, dysphoria, and nightmares.[49] Only 3.2% of patients treated with either drug discontinued the medication because of side effects. Another head-to-head trial showed similar types and rates of adverse effects for IR methylphenidate and IR dextro/levo amphetamine.[50]

Table 89-3

Managing Adverse Effects of Stimulants Used in Children with Attention Deficit Hyperactivity Disorder

Adverse Effect	Management
Decreased appetite, nausea, or growth impairment	■ Schedule evening meals after medication has worn off ■ Take drug after meals ■ Encourage foods with high caloric density or nutritional supplements ■ Encourage evening/bedtime snack ■ Switch from long-acting to short-acting preparation ■ Consider a drug holiday when appropriate
Sleep disturbance	■ Administer doses earlier in the day ■ If using a sustained-release product, consider changing to a short-acting preparation ■ Discontinue afternoon/evening dose
Behavioral rebound	■ If using short-acting preparation, consider changing to a long-acting preparation ■ Overlap stimulant dosing

Irritability	■ Assess time of symptoms:
	  ■ Related to peak: reduce dose or try long-acting preparation
	  ■ Related to withdrawal: change to long-acting preparation
	■ Evaluate for comorbid diagnosis

Dysphoria, moodiness, agitation, dazed, or withdrawn behavior	■ Decrease dose or change to long-acting preparation ■ Consider comorbid diagnosis
Dizziness	■ Monitor blood pressure ■ Encourage fluid intake ■ Lower dose or change to long-acting preparation to reduce peak effects
Development or increase in tic disorder	■ Stop stimulant ■ Consider trial of clonidine or guanfacine ■ Consider referral to physician

There is an association between stimulant use and growth retardation. The relative impact of this seems minimal and can be reduced or eliminated with drug holidays.[51–53] There seems to be no loss of efficacy if the child does have a drug holiday and stops the medication over weekends holidays or summer months.[54] The risk of drug holidays is a worsening of symptoms and this may have impact on social maturation.

There was concern that the stimulants may have a cardiotoxicity risk. Population studies suggest, however, that the overall risk of sudden death associated with stimulant use has been shown to be the same, if not lower, than that of the general population.[55] Slight increases in BP and HR are seen with methylphenidate and amphetamines, although ECG changes are very rare.[56–58] Clinicians should follow current recommendations suggested by the American Academy of Pediatrics and the American Heart Association, which advocate screening for a personal or family history of cardiovascular disease in all children with ADHD. Continual monitoring for these risks along with routine blood pressure and heart rate assessments should be performed.[59] Pretreatment ECGs are not required but recommended by the AHA as general practice for all children. Stimulants should not be used in those with known structural cardiac abnormalities.[60]

NON-STIMULANTS

For patients with ADHD only, it is recommended to initiate treatment with either a methylphenidate or an amphetamine.[2,32–34] For patients who fail both types of stimulants or when stimulants are not preferred, a trial of a non-stimulant is warranted (Table 89-2). Non-stimulants are less effective than stimulants and usually require at least 4 weeks until a full response is evident. A meta-analysis of 29 double-blind, placebo-controlled trials evaluated the efficacy of stimulant and non-stimulant agents using 17 outcome measures in 4,465 children and adolescents with ADHD.[61] It found that the effect size of amphetamine and methylphenidate was significantly greater than that for atomoxetine, bupropion, and modafinil ($p = 0.02$).[61] If atomoxetine fails or is not indicated, the α_2-adrenergic agonists clonidine and guanfacine should be considered.[31–33]

Atomoxetine

Atomoxetine inhibits the presynaptic norepinephrine transporter and is classified as norepinephrine reuptake inhibitor (NRI). Clinical trials have shown that atomoxetine is superior to placebo in reducing the symptoms of ADHD in children, adolescents, and adults.[62,63] However, trials comparing atomoxetine with stimulants have found atomoxetine to be less effective.[2,64–67]

Atomoxetine is likely to have some immediate benefit after initiation but unlike the stimulants a longer trial of 6 to 8 weeks is recommended as efficacy continues to grow. Atomoxetine requires a 10- to 14-day titration to achieve a therapeutic dose of 1 to 1.5 mg/kg/day to avoid nausea (12%), vomiting (15%), and asthenia (11%).[68] As with stimulants, atomoxetine can also raise blood pressure and heart rate, with reports of high systolic and diastolic blood pressures occurring in 8.6% and 5.2% of pediatric subjects, respectively. Increases in heart rate of more than 110 beats/minute and more than 25 beats/minute above baseline were observed in 3.6% of patients.[68] Atomoxetine is metabolized via CYP 450 2D6, with the major metabolite being 4-hydroxyatomoxetine which is also a potent inhibitor of NE reuptake but at low concentration levels. It has a half-life of 4 to 5 hours but can be extended by about 3 hours with a high fat meal.[69]

There have been postmarketing cases of reversible hepatic injury in association with atomoxetine, but this is quite rare.[70] Baseline liver enzyme testing should be performed, and evidence of jaundice or liver injury should warrant immediate discontinuation. Atomoxetine also contains the warning regarding increased risk of suicidal thoughts that are part of all antidepressant class labeling. However, a meta-analysis of 14 trials found that no subject committed suicide. Suicidal ideation in the atomoxetine group was 5/1,357 (0.37%) and placebo group was 0/851 (0%).[71] So, despite the low risk, monitoring frequently for the first 3 months of treatment is required by the FDA.

α_2-Agonists

Clonidine and guanfacine are α_2-agonists that have been used for years off-label to control hyperactive/impulsive or aggressive symptoms and insomnia.[72] They are believed to directly stimulate the postsynaptic norepinephrine receptors in the prefrontal cortex and locus coeruleus. Guanfacine is most specific for the α-2a receptor, while clonidine is less specific and agonizes α-2a, b, and c. The FDA has approved extended-release formulations for clonidine and guanfacine both as monotherapy and as adjuncts to stimulants. Clonidine and guanfacine are also approved as adjuncts to stimulants for ADHD. Although they are a monotherapy option, they are not considered as first line as they are less effective than stimulants.

They are particularly useful for behavioral comorbidities, such as aggression and tics.[31–34,73–75]

Guanfacine is primarily metabolized via CYP 3A4, and potent inhibitors can increase blood levels by 200%. Guanfacine extended release provides approximately 60% of the serum levels of the immediate-release version. Clonidine is partially metabolized via CYP 2D6, although inhibitors of this pathway have only minor changes in serum levels.[76] The extended-release version has an AUC approximately 89% of the immediate release.

The side effect profile of α-2 agonists is quite different than the stimulants and atomoxetine. Sedation and related side effects can occur in nearly 40% for both. Reductions in BP and HR can occur and need to be monitored. Bradycardia (HR < 60 bpm) can occur in up to 20% of children with clonidine and is a side effect of guanfacine also but to a lesser degree. This is likely because of guanfacine's specificity to α 2a. Rebound hypertension can occur if either of these medications are stopped abruptly.[73]

Despite positive studies with immediate-release formulations, the short duration of action makes them less desirable than the QD dosing of guanfacine ER and the BID dosing clonidine extended-release formulation.[32]

CASE 89-1, QUESTION 4: It is agreed upon by the parents and the pediatrician that M.T., the 12-year-old female, will begin using a medication for her ADHD symptoms. What would be the first-line option for M.T.?

Either stimulant groups are considered first line and in this case methylphenidate 10 mg qam is tried. After steadily increasing the dose to 30 mg qam the parents feel that there is minimal change in attention, but that there are significant side effects of nausea and loss of appetite.

CASE 89-1, QUESTION 5: What would be the next trial of medication for M.T.?

Expert guidelines state that if medication is decided upon then the greatest efficacy is from the stimulants. Neither stimulant is considered superior to the other and initial choice should be based on the comfort level of the clinician and patient/parent acceptance. If the initial choice of stimulant is ineffective, it is recommended to trial the other stimulant class. By doing this 90% of children will display efficacy. Therefore, the next trial for M.T. should be the initiation of dextroamphetamine 5 mg qam and titrate as tolerated to a maximum of 40 mg a day.

CASE 89-1, QUESTION 6: M.T. is showing some improvement on 10 mg qam of immediate-release dextroamphetamine, but it is clearly wearing off about 4 hours after dosing. Dosing of 10 mg BID was tried during a school vacation and found to be somewhat effective; thus, the pediatrician decided to switch to long-acting dextroamphetamine spansules 20 mg qam. This clearly has shown to last throughout M.T.'s school day, but efficacy is not maximized and some residual symptoms of poor attention and hyperactivity exists. What is the next step of pharmacotherapy for M.T.?

Increasing the dose to 30 mg qam is possible. Although a switch from a stimulant to atomoxetine could be tried, data have shown that atomoxetine is less effective than stimulants. Experts recommend that combination therapy of a stimulant and an α-2 agonist is appropriate, and studies have shown an increase in efficacy from monotherapy to combination therapy.

Comorbidities

TOURETTE'S SYNDROME AND TIC DISORDER

Tourette's syndrome is neuropsychiatric condition which has tics as a hallmark symptom. Children with ADHD have a higher risk of comorbid tic disorder than the general population; however, stimulants are relatively safe in this population. As an example, the Tourette's Syndrome Study Group contrasted the effect of methylphenidate, clonidine, and the combination of the two to placebo in the treatment of 136 children (7–14 years old) diagnosed with ADHD and Tourette syndrome.[77] The group concluded that prior recommendations to avoid methylphenidate in these children because of concerns of worsening tics were unsupported. As such, expert recommendations are that a child with ADHD should start on methylphenidate, and if tics emerge or worsen then a switch to atomoxetine or clonidine is warranted. A meta-analysis of studies with subjects who have ADHD and Tourette's syndrome concluded that methylphenidate shows the greatest improvement in ADHD symptoms without worsening tics in most kids. α-2 Agonists offer less efficacy in ADHD symptoms but greater control over tics compared to methylphenidate. Atomoxetine offers benefit on both groups of symptoms and is an option.[32,74,75] Amphetamines should be avoided because although they do treat ADHD symptoms, they have a higher chance of worsening tics compared to methylphenidate.[74,75]

A review regarding treatment of tic disorders without comorbid ADHD states that the α-2 agonists guanfacine and clonidine are recommended as first-line options. Guanfacine may be preferred because of less sedation than clonidine.[78]

ANXIETY DISORDER

Anxiety disorders are more frequently comorbid in the ADHD child (approximately ninefold) and adult (approximately fourfold) compared to the frequency seen in the general population. Despite the fact that the anxiety disorder may be a separate illness, anxiety symptoms in the child can be directly related to poor performance because of ADHD symptoms. Treatment with a stimulant that subsequently improves performance will reduce the anxiety. However, some children after a trial with a stimulant will not have an anxiety reduction or it may even worsen. At this point a trial with atomoxetine is recommended over treating the anxiety with an SSRI and continuing the stimulant.[2,79]

SUBSTANCE ABUSE

Despite the fact that stimulants are medications with an abuse risk, multiple studies have shown a protective effect against developing a substance-use disorder with children who derive a benefit to their ADHD symptoms from the medication. A meta-analysis of epidemiologic literature led to the conclusion that stimulant-treated patients with a diagnosis of ADHD were less likely to be diagnosed with substance-use disorder than those not treated with stimulants.[80] Using a stimulant for ADHD in a current substance abuser has contradictory results. Stimulants do treat the ADHD symptoms but not as robustly as those without a concurrent substance-use disorder. They do not seem to reduce the substance use but clearly do not worsen it.[81] Expert opinion suggests that those with current substance-use disorders should be tried on non-stimulant options first, but stimulants are not fully contraindicated and can be used with close monitoring. There is growing data to support that there is a high rate of diversion of stimulants in the college population. One report correlated an increased incidence of diversion with increased difficulty of the academic program.[32,82,83]

If misuse and diversion are of concern, methylphenidate comes as a transdermal patch formulation, and dextroamphetamine is available as a hard to abuse prodrug lisdexamfetamine.[32,34,43,44,46]

Despite the potential for being less effective than a stimulant, atomoxetine has preferred benefits in specific patient subtypes. Because it is not a stimulant, its risk of abuse and diversion are low and is preferred in patients with an addictions disorder history or living in a household where someone other than the patient (e.g., parent or sibling) has an addiction disorder and may take the patients medications.

PSYCHOSIS

Stimulants may cause psychosis. This is because of the enhancement of DA centrally. If the child is acknowledging hallucinations or exhibiting bizarre behavior then cessation of the stimulant is required. A rechallenge can occur but at a lower dose. If a child stabilized on the medication starts to exhibit psychotic symptoms then one should assess for drug interactions. The methylphenidate transdermal patch formulation can have greater unexpected fluctuations in blood levels because of a greater range of absorption compared to the oral formulations.[42,43] The absorption of the transdermal patch is influenced by placement site and temperature of the skin. Treating this side effect with an antipsychotic is not recommended.[32]

Other Non-FDA Pharmacotherapy

BUPROPION

Bupropion has been shown to be effective compared to placebo, but it is less effective than stimulants in treatment of ADHD.[67] Randomized, controlled trials have established the effectiveness of bupropion as an alternative to the psychostimulants in the treatment of ADHD in children, adolescents, and adults.[84–86] The two most common adverse effects encountered with bupropion in ADHD studies were dermatologic reactions and seizures. Dermatologic reactions occurred twice as often with bupropion compared with placebo. Severe bupropion-induced urticaria required discontinuation in 5.5% (4 of 72) of the patients in one study.[87] In adults, the risk of seizures increases by about fourfold if extended-release doses of greater than 450 mg/day or greater than 400 mg/day sustained-release doses of bupropion doses are exceeded.[88] Although there are no case reports of seizures in children receiving therapeutic doses of bupropion, it is recommended to limit doses to less than 6 mg/kg/day in the treatment of ADHD and to avoid using bupropion in patients with a history of seizure disorders.

MODAFINIL

Modafinil has been found to be effective in the treatment of prepubescent, adolescent, and adult patients with ADHD.[89,90] The 2006 Pediatric FDA advisory committee reviewed the efficacy and safety of modafinil for ADHD and determined the drug was effective but rejected its approval for ADHD based on concerns about safety. Twelve of 933 patients developed a skin rash, with one case thought to be Stevens–Johnson syndrome.[91]

TRICYCLIC ANTIDEPRESSANTS (TCAS) AND SEROTONIN AND NOREPINEPHRINE REUPTAKE INHIBITORS (SNRIs)

As recently as 2007 guidelines reported, TCAs could be an option for ADHD. However, their poor tolerability and dangerous effect on cardiac conduction has resulted in more recently published guidelines in 2011 and 2014 to not recommend them.[2,32–34]

The SNRI venlafaxine has shown efficacy in both adolescents and adults with ADHD. This is a legitimate choice for comorbid anxious or depressed older patients, but because of antidepressants having a risk of increasing suicidal thinking in children, other options should be tried first. Adults often have this comorbidity and venlafaxine in that population is more likely to be used.[32]

Alternative Therapy

There have been a number of studies that have tried to discern if certain diets may result in ADHD. One of the most famous regimens is the Feingold Diet. Recent reviews on the topic have found the evidence to be of low quality and of small benefit. Most studies have not been blinded and when efficacy is noted it is of lower rates than the FDA-approved pharmacotherapies. Additionally, there is a practical limitation to the implementation of these diets as it eliminates many of the foods that are regular parts of American meals. At this time it does seem reasonable to assume that some children's ADHD-like behavior may be related to intolerance to certain dyes, artificial sweeteners, and flavors. One should not discourage a parent to promote healthier food selection for their child, but the effectiveness of lowering their symptoms is marginal. Additionally, if a child has a delay in administration of pharmacotherapy because of trials of different types of diets then this could result in persistency of symptoms longer than is necessary.[92]

Many companies have created dietary supplements that have been touted as effective remedies for treating and preventing ADHD, but convincing results derived from rigorous trials are currently lacking and are likely to benefit a very few children with food allergies or intolerances.[92–94] For instance, the use of very high doses of vitamins or minerals has been promoted as a possible intervention, but all randomized, controlled trials conducted to evaluate the effectiveness of megavitamin therapy have been negative to date.[95] Omega-3 fatty acids have been considered as possible treatments for ADHD, based largely on population studies demonstrating an association between high dietary intake and a reduced risk of various neuropsychiatric disorders. Omega-3 supplementation, specifically EPA content, may have a small benefit as monotherapy. Studies of omega-3 as an adjunct to stimulants have shown little added benefit.[96,97] Similarly, there have been reports of zinc, iron, magnesium, Hypericum (St. John's wort), and gingko all relieving ADHD symptoms, but the evidence to support these interventions is very limited at the present time.[98]

There have been other somatic treatments aimed at relieving ADHD symptoms that may prove to be beneficial in the years ahead.[98] Several small randomized studies have reported benefits with neurofeedback, in which children are trained to modify certain brain activities demonstrated on electroencephalographic tracings (e.g., increased slow wave or α activity). Preliminary evidence also supports the exploration of meditation as an effective intervention for ADHD, particularly mindfulness-based methods that have proven to be particularly helpful for depression and chronic pain conditions.[99] Clinic-based interventions have included cognitive-behavioral therapy, social skills training programs and computer-based cognitive training programs. Early studies of some of these intervention strategies have been promising and there is need for further research to establish efficacy.[35] Regarding acupuncture a recent systematic review failed to find any studies of sufficient rigor to include in their analysis.[100]

ADULTS WITH ATTENTION DEFICIT HYPERACTIVITY DISORDER

CASE 89-2

QUESTION 1: K.C. is a 27-year-old female who is an adjunct professor in a pharmacy program and comes to a retail pharmacy wanting to fill a prescription for dextroamphetamine IR 10 mg tid #90. What are the treatment recommendations for an adult with ADHD?

It is estimated that two-thirds of children with ADHD will continue to have significant symptomatology as adults.[11] Often the hyperactivity/impulsivity aspect of the illness becomes less pronounced once the child hits adolescence, but the symptoms of inattention persist into adulthood.[6] Even though many of the children with ADHD may no longer satisfy strict diagnostic criteria for ADHD as adults, the severity and persistence of inattentive symptoms can continue to cause considerable social and functional disability. One investigation followed 128 children with ADHD for several years and reported that hyperactivity and impulsivity symptoms were seen to decline at a higher rate than inattention symptoms.[6] Other researchers have followed children with ADHD to adulthood by comparing the academic records of control subjects and ADHD adults. The latter had significantly higher rates of repeated grades, tutoring, placement in special classes, and reading disability.[101,102] Children with ADHD will have greater morbidity in psychosocial and educational areas in adulthood compared to adults who did not have ADHD as children.[103] Adults with ADHD have been found to achieve lower socioeconomic status and experience more work difficulties and more frequent job changes.[104] Adults with ADHD reported more psychologic maladjustment, more speeding violations, and more frequent changes in employment.[105] More adults with ADHD had their driver's licenses suspended, had performed more poorly at work, and had quit or been fired from their job. Adults with ADHD were also more likely to have had multiple marriages.[11]

The diagnostic criteria for ADHD in adults are the same as for children and adolescents (DSM-5).[4] However, only five of either hyperactivity/impulsivity or inattention must be present for a minimum of 6 months, impairing function in two or more settings. A diagnosis of ADHD in adults also requires evidence that symptoms were present before the age of 12. One study compared the functional outcomes of adults with ADHD before age 7 with adults, who had the requisite symptoms but lacked conclusive evidence of childhood onset. The investigators found no difference between the two groups in primary outcomes such as learning disabilities, arrests, motor vehicle accidents, and divorce.[106]

Current treatment recommendations for ADHD in adults continue to support pharmacotherapy as the first-line option for moderate-to-severe symptoms.[32] Although benefits have been noted for psychotherapeutic approaches such as cognitive behavioral therapy and dialectic behavioral therapy, these interventions are recommended only for adults exhibiting suboptimal response to approved medications.[107,108]

A variety of medications have been reported to be beneficial for ADHD in adults, including methylphenidate, dexmethylphenidate, mixed amphetamine salts, lisdexamfetamine, desipramine, bupropion, atomoxetine α-2 agonists, venlafaxine, and modafinil.[85,90,109–116] The stimulants and atomoxetine are FDA approved in adults.[32] In general, the effect sizes for these ADHD medications in adults have been very similar to what has traditionally been reported in children. A meta-analysis of medications for ADHD in adults found that long-acting stimulants were significantly more effective than non-stimulant drugs, but that the effectiveness of shorter-acting stimulants was comparable to the latter.[9] The authors also noted that lower doses appeared to be more effective for inattention than hyperactivity. For example, doses for immediate-release methylphenidate were more conservative (0.3 mg/kg per dose in adults) when inattention was the predominate feature. In contrast, doses of up to 0.6 mg/kg immediate-release methylphenidate were often necessary to optimally control the behavioral feature of the disorder in children.[117] These methylphenidate doses are consistent with 0.5 to 1.0 mg/kg/day doses found to be effective in children.[110] Mixed amphetamine salts were effective in doses of 20 to 60 mg/day.[111] The effective dose of desipramine was approximately 150 mg/day.[114] Bupropion was generally dosed at 3 mg/kg/day.[85] The two large studies of atomoxetine used doses that ranged from 60 to 120 mg/day.[114,115] The mean effective dose for modafinil was 207 mg/day.[90]

Treatment with stimulants or atomoxetine have shown improvements in reduced criminality and driving accidents.[118–121]

CASE 89-2, QUESTION 2: Before filling the prescription for K.C. the pharmacist reviews it and finds that it is written within 30 days. He also checks the prescription drug monitoring program in his state and finds that she has filled a prescription for the same drug and directions 25, 28, 54, and 56 days ago at other retail pharmacies. These double fills are also written by two different physicians.

What would be an appropriate response by the pharmacist to K.C.'s request?

As noted above, ADHD symptoms can persist into adulthood for many children. A positive history of either an ADHD diagnosis or untreated symptoms in childhood is required for an adult to be diagnosed with ADHD. However, many other diseases can lead to a false positive. Complete blood counts, urine toxicology, and head injury must all be evaluated along with psychiatric conditions such as bipolar disorder, anxiety disorders, and major depressive disorder.[122] Also, one cannot rule out the possibility of substance-use disorder. As with other drugs that have an abuse liability, stimulants can either be abused by the patient or diverted and sold to those who want to use them for their euphoria-inducing effect instead of helping treat ADHD. There is an increasing amount of data reporting the intermittent use of stimulants by college students for study enhancement and abuse, particularly when mixed with a sedating drug of abuse. Therefore, the pharmacist should consult with the clinician who wrote the prescription alerting him to the recent fill at another pharmacy. It is quite possible that this new prescription is legitimate, but it is also possible that K.C. is misusing the dextroamphetamine herself or diverting them to others. A reevaluation of her diagnosis is necessary. If it is confirmed that the patient does have ADHD then options would be to switch to a less abusable stimulant such as lisdexamfetamine or methylphenidate transdermal patch. Switching to the non-abusable atomoxetine is recommended because even though these stimulant formulations are less abusable they are not devoid of abuse risk. Atomoxetine or the non-FDA adult approved agents such as α-2 agonists or bupropion, venlafaxine, and modafinil will likely be less effective than the stimulant for ADHD but provide a safer abuse-risk possibility.

Substance Use Disorders

Michael C. Angelini

CORE PRINCIPLES

		CHAPTER CASES
1	Substance use disorder is a chronic disease with progressive deterioration of psychological and physiologic activity secondary to the habitual use of a drug. This complex disease disrupts many if not all aspects of an individual's life; therefore, multimodal treatment is necessary.	**Case 90-1 (Question 1), Case 90-11 (Question 1), Table 90-1**
2	Opioid misuse includes illicit drugs, such as heroin, and the nonmedical use of prescription pain relievers. Opioid withdrawal is characterized as a flu-like syndrome, involving nausea, vomiting, sweats, diarrhea, pain, and elevations in pulse and blood pressure. The full agonist methadone, partial agonist buprenorphine, and antagonist naltrexone all can be used as maintenance therapy to reduce relapses. Treatment considerations during pregnancy consist of fetal risks if the mother goes into opiate withdrawal or if the mother relapses into addictive behavior. Neonatal abstinence syndrome occurs in the newborn if the mother has been maintained on methadone or buprenorphine.	**Case 90-2 (Question 1), Case 90-3 (Question 1), Case 90-4 (Question 1), Case 90-5 (Question 1), Table 90-2**
3	Sedative-hypnotic drugs of abuse include benzodiazepines, barbiturates, some skeletal muscle relaxants, such as carisoprodol, and γ-hydroxybutyric acid (GHB). Withdrawal symptoms, similar to those of alcohol withdrawal, may include tremors, insomnia, anxiety, elevations in pulse and blood pressure, seizures, and hallucinations, and may be potentially life-threatening. In clinical practice, three general medication strategies are used for withdrawing patients from sedative-hypnotics: gradual tapering of the drug of abuse, substituting and gradually tapering phenobarbital, and substituting and gradually tapering a long-acting benzodiazepine.	**Case 90-6 (Question 1), Table 90-3**
4	Major central nervous system (CNS) stimulants of abuse include cocaine and amphetamines. These drugs are associated with serious acute and chronic adverse effects, such as hyperthermia, paranoia, psychosis, hypertension, arrhythmias, myocardial infarction, seizures, and strokes. Withdrawal from stimulants is not associated with severe symptoms. Primarily, withdrawal consists of fatigue and hypersomnolence. There is currently no US Food and Drug Administration (FDA)-approved treatment for withdrawal or maintenance treatment of stimulant use disorder.	**Case 90-7 (Questions 1, 2)**
5	The use of hallucinogens, including LSD, psilocybin, mescaline, and	**Case 90-8 (Questions 1–3)**

	MDMA, may result in psychological, but not physical, dependency. Adverse reactions during intoxication, such as anxiety, paranoia, and fear, may necessitate benzodiazepine or antipsychotic therapy, but are best managed using a “talk-down” method.	
⑥	Marijuana is a widely used substance. The withdrawal syndrome is generally mild, characterized by anxiety, depression, irritability, and insomnia, and does not require treatment. Chronic use has been shown to result in increased risks of car accidents, pulmonary complications, psychosis, and anxiety.	**Case 90-9 (Questions 1–3)**

⑦	Alcohol use disorder is defined by acute and chronic alcohol use. It can result in toxicity, withdrawal, and addiction. Alcohol toxicity is an acute, life-threatening condition that requires aggressive medical attention. Symptoms include a strong smell of alcohol, risk of aspiration, depressed and shallow respiration, and cardiac arrest. Management generally consists of respiratory support and a thorough diagnostic evaluation to rule out coingestion of other drugs or other underlying medical conditions that may also need attention.	**Case 90-10 (Question 1), Tables 90-4, 90-5**
⑧	Alcohol withdrawal is the neurobiological syndrome associated with increased tolerance or physical dependence resulting from chronic alcohol consumption. This syndrome results in a continuum of signs or symptoms including paresthesias, headache, nausea, anxiety, shaking, increased heart rate and blood pressure, and seizures. Symptom-triggered assessment and treatment of alcohol withdrawal is extremely important since untreated withdrawal can result in death. Treatment may be complicated not only by the physical or cognitive deterioration that can occur but also by the lack of attention to other serious medical or psychological conditions that could be contributing to, or resulting from, chronic alcohol use. Adjunctive treatments including fluid (e.g., normal saline solution), nutritional (e.g., thiamine, folic acid, multivitamins), and electrolyte (e.g., magnesium, potassium) replacement should also be initiated to address the physiological consequences of chronic alcohol use.	**Case 90-10 (Questions 2–4), Table 90-6**
⑨	Chronic alcohol use disorder (alcohol dependence) is a life-long relapsing disorder that consists of signs of alcohol abuse (continued drinking despite alcohol-related physical, social, psychological, or occupational problems, or drinking in dangerous situations, such as while driving) to the extent that the person also experiences at least three of the following seven symptoms: neglect of other activities, excessive use of alcohol, impaired control of alcohol consumption, persistence of alcohol use, large amounts of time spent in alcohol-related activities, withdrawal symptoms, and tolerance of alcohol. Approved pharmacotherapies include disulfiram, naltrexone (tablets and injection), and acamprosate. Which option is best is determined by many factors such as home support, medical comorbidities, and concomitant medications.	**Case 90-11 (Question 1), Tables 90-4, 90-6**

SUBSTANCE USE DISORDER

Physical dependence occurs when repeated administration of a drug causes an altered physiologic state (neuroadaptation). After neuroadaptation, a characteristic set of withdrawal symptoms occurs when the drug is abruptly discontinued. Psychological addiction or psychological dependence refers to a "maladaptive pattern of substance use leading to clinically significant impairment or distress."[1] Habituation is a state of either chronic or periodic drug use characterized by a desire (but not a compulsion) to continue using the drug, no tendency to increase the dose, and an absence of physical symptoms despite some degree of psychological dependence. A different clinical syndrome is associated with each drug, but all involve a chronic process with progressive deterioration of psychological and physiologic activity secondary to the habitual use of a drug. Addiction is not a diagnosis but is defined by the American Society of Addiction Medicine as a chronic disease of brain reward, motivation, memory, and related circuitry. Dysfunction in these circuits has biological, psychological, social, and spiritual effects. There is a pathologic pursuit of the substance with an inability to abstain, loss of control, craving, and diminished recognition of the intensity of the problem. It is cyclical with periods of relapse and remission. Without treatment, it is significantly disabling and will result in premature death. Addiction is frequently used as a descriptor of the most disabling and intense form of a substance use disorder.[2] Although the neurochemistry of the addictive process is possibly the same for all drugs, the psychosocial and pharmacokinetic aspects vary from drug to drug. Evidence, consistent with models established for alcoholism, indicates that genetically inherited traits may result in expression of addictive disease when the person is exposed to certain drugs and other habituating psychic stimuli.[3]

CASE 90-1

QUESTION 1: R.L., age 26, was recently arrested for possession and driving under the influence (DUI) oxycodone. This is his second DUI offense in the last year. R.L. does not use oxycodone daily, but admits to weekly use. Does R.L. meet the criteria for a diagnosis of a substance use disorder?

The Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5) cites criteria for substance-related disorders and divides them into two groups: the substance use disorders Table 90-1) and the substance-induced disorders (intoxication, withdrawal, and others).[1] In 2014, an estimated 27 million persons age 12 or older were classified as current illicit drug users.[4]

Pharmacologic treatment is only one aspect of the management of substance use disorders. Treatment of withdrawal (when needed depending on the chemical of abuse) is the first step in management and should be followed by individualized, psychosocial treatment that is effective in the least restrictive and most cost-effective manner. A strong therapeutic alliance between care provider and patient based on a supportive, empathic, nonjudgmental, clinically appropriate relationship is predictive of successful therapy outcomes. Substance use disorder is a complex disease that disrupts many if not all aspects of an individual’s life. Therefore, multimodal treatment is necessary. Psychosocial therapies that may or may not include pharmacologic agents consist of individual as well as group counseling, cognitive-behavioral therapies (learning triggers for use, new coping mechanisms, and relapse prevention), motivational enhancement therapies, family counseling, and voucher-based reinforcement therapy among others. These therapies are often augmented with involvement in support groups, such as 12-step programs.[3]

Table 90-1

American Psychiatric Association, Diagnostic and Statistical Manual of Mental Disorders, Criteria for Substance Use Disorders

The patient must display 2 of the following in the last 12 months
Consuming larger amounts of the substance[a] or over a longer period of time than was intended
Persistent desire to reduce substance use or unsuccessful efforts to cut down or control use
A great deal of time is spent in activities necessary to obtain, use, or recover from the effects of the substance
Craving or a strong urge to use the substance
Recurrent use results in failures to fulfill obligations at work, school, or home
Continued substance use despite having persistent social and interpersonal problems created or made worse by the use of the substance
Important social, occupational, or recreational activities are given up or reduced because of the substance use
Recurrent substance use in situations that are physically hazardous
Substance use is continued despite knowledge of having persistent or recurrent physical or psychological problems caused or worsened by the substance
Tolerance defined by either of the following:
A need for increased amounts of the substance to achieve intoxication or desired effects
A markedly diminished effect with continued use of the same amount of the substance
Withdrawal as defined by either of the following:
The characteristic withdrawal syndrome for the substance
The withdrawal syndrome is alleviated by taken a closely related substance (e.g., using a benzodiazepine for alcohol withdrawal)

[a] Substance is defined as any drug, including alcohol.

Source: American Psychiatric Association. Diagnostic and Statistical Manual of Mental Disorders, (DSM-5). 5th ed. Washington, DC: American Psychiatric Publishing; 2013.

R.L. has a pattern of oxycodone use in situations in which it is physically hazardous, as well as two arrests in the last year for DUI. R.L. meets the DSM-5 criteria for substance use disorder.

OPIOIDS

Abuse of opioids includes illicit drugs, such as heroin, and the nonmedical use of prescription pain relievers. According to the Drug Enforcement Administration (DEA), prescription pain relievers appear to be increasingly diverted from legitimate and illegitimate sources of supply via the internet.[5] The 2014 National Survey on Drug Use and Health reports, among persons age 12 years or older, that there are 4.3 million nonmedical use of pain relievers.[4] The non–FDA-approved opiate heroin is produced in four major source areas, South America, Mexico, Southeast Asia, and Southwest Asia. Mexico has been the predominant supplier to the west coast of the United States and is expanding distribution in eastern US markets as South American production has decreased.[6] Mexican heroin black tar is potent, 40% to 80% pure, but contains more plant impurities than the white powder refined heroin from Asia or South America.[7] The purity of available heroin enables a new, younger user population, who can smoke or snort this high purity heroin and avoid the stigma and hazards associated with needle use. As the substance use disorder intensifies and the user's "habit" (amount used daily) increases, the user will often begin injecting the drug. The Centers for Disease and Prevention (CDC) estimates there are roughly 900,000 persons who have used heroin in the last year in the United States. The 2014 National Survey on Drug Use and Health found that usage of heroin has increased since the early 2000s mostly driven by the 18- to 25-year age group.[4] Some prescription opioid abusers will eventually switch to using heroin, because it is less expensive.

Opioid Use Disorder

Physical dependence occurs in any patient after a few days of continuous administration of an opioid. In the management of acute pain, opioid dependence is generally not clinically significant because the patient is tapered off opioid analgesics naturally because the pain condition resolves. If the opioid is abruptly stopped, the patient may experience withdrawal symptoms; however, the intensity of those symptoms varies depending on the individual's physiology, as well as the dose and duration of use of the opioid. Although the exact dose and duration of opioid administration required to produce clinically significant physical dependence is not known, higher doses and longer times of administration correlate with more severe symptoms of withdrawal on cessation of opioid use.

Physical dependence is defined as a neurobiological adaptation that occurs with chronic exposure and occurs with many drug classes regardless if they have an abuse potential (e.g., β-blockers, steroids, SSRIs). Physical dependence and tolerance (the need for increasing doses to achieve the initial effects of the drug) can occur in the setting of substance use disorder, but are also expected, nonpathological sequelae of chronic opioid therapy.

Most studies evaluating the occurrence of opioid use disorder resulting from the therapeutic treatment of pain have concluded the risk is low.[8] Historically, a much greater problem has been the undertreatment of pain. Yet, people at risk environmentally or predisposed genetically for substance use disorder may have their first exposure through a legitimate, therapeutically dosed prescription of an opiate for an acute pain syndrome. This then progresses to an inappropriate use of the opiate and resultant substance use disorder. Thus, pain management with opiates needs careful monitoring (see Pain Management Chapter 55).

Certain pharmacologic properties, such as high potency, rapid onset and shorter duration of action, and water solubility, may increase the likelihood of abuse of that medication. Although all opioids have some abuse liability, some are intrinsically more abusable than others. For example, the controlled-release formulations have been promoted as less likely to cause substance use disorder than immediate-release products, because some of the reinforcing properties, like multiple peaks and troughs, of the opioid are reduced. When tablets, such as OxyContin, are crushed, however, the drug's controlled-release properties are compromised, and the result is much higher dosages than what is available in the immediate-release formulation tablets. Despite the manufacturer's attempts at altering the formulation of OxyContin to make it harder to tamper with, this product can still be abused. Mixed agonist–antagonist opioids (pentazocine, nalbuphine, butorphanol, buprenorphine) have less potential for misuse than the pure mu agonists (e.g., morphine, hydromorphone, oxycodone); however, misuse to all has been observed.[8] Other options to reduce diversion and misuse are formulary management strategies that help the clinician limit opiate prescriptions.[9,10] In total, the best method of reducing this problem is a combination of psychosocial therapy, pharmacotherapy, and policy.

The term "pseudoaddiction" has been coined to describe the inaccurate interpretation of certain "drug-seeking behaviors" in patients who are inadequately treated for pain.[8] Their preoccupation actually reflects a need for pain relief, but is erroneously interpreted as a severe substance use disorder (addiction).

Medical Complications

The common practice of sharing needles and syringes between friends has resulted in transmission of various infectious diseases. Chief among those is viral hepatitis, specifically the hepatitis C virus (HCV). According to the CDC, in the United States, human immunodeficiency virus (HIV) infection caused by injection drug use had an overall prevalence of 6% in 2015.[11] Other infectious diseases such as syphilis, tetanus, botulism, and malaria can be transmitted in a similar manner and should be considered when evaluating these patients. When heroin is prepared for self-administration, cotton is used as a filter to trap adulterants; thus, some of the drug remains trapped in the cotton. These crude filters are saved, and when money or drug availability is poor, water or other solvents are added to the "old cottons" to extract any remaining drug for intravenous (IV) use. "Cotton fever" is an acute febrile reaction. The onset is within 30 minutes of injection, with shaking chills, diaphoresis, postural hypotension, tachycardia, and low-grade fever. These symptoms are initially suggestive of sepsis, but most of the symptoms resolve without treatment in 2 to 4 hours, with complete recovery in 1 day. The causal agent is probably Pantoea (formerly Enterobacter) agglomerans, via a heat-stable endotoxin.[12] Cotton and cotton plants are heavily colonized with P. agglomerans.[13] IV drug users will often use the term cotton fever to describe any short-term illness characterized by fever, chills, aches, and pains.[14]

Opioid Toxicity/Overdose

CASE 90-2

QUESTION 1: T.F., a 21-year-old man, was found unconscious after an alleged "OD" (overdose) on heroin. He had a decreased respiratory rate of 4 breaths/minute, cyanosis, symmetrically "pinned" (maximally miotic or pinpoint) pupils, and a slightly decreased blood pressure, 117/72 mm Hg. He has one needle puncture wound and several old needle marks and healed scars in the antecubital fossa area. What is the immediate treatment of choice for this patient?

Immediate treatment includes airway management, cardiorespiratory support, and opioid reversal with naloxone. Naloxone is a full opioid competitive antagonist that rapidly reverses the respiratory depression and hypotension associated with overdose. The preferred route of administration is IV; if access cannot be gained, it may be given intramuscularly (IM), subcutaneously (SC), intranasally, or by endotracheal tube. Intranasal use by first responders and friends or family members of those who have overdosed has shown to have saved lives.[15–17]

Initial IV administration of 0.2 to 0.4 mg naloxone should be slow and should be discontinued if T.F. responds. It is not necessary to precipitate opioid withdrawal symptoms; the end point of naloxone therapy is a relative stabilization of the patient's vital signs. A naloxone-precipitated, sudden-onset withdrawal syndrome is more severe than the symptoms produced by abstinence alone. Repetitive doses should be given if the patient remains unresponsive, up to a maximal dose of 10 mg of naloxone.[15] If the patient still has not responded, the diagnosis of opioid overdose should be reconsidered.[15]

The duration of action of naloxone ranges from 20 to 60 minutes, depending on the dose and route of administration. Treatment of the methadone-overdosed patient will require serial dosing of naloxone every 20 to 60 minutes because the toxic effects of this long-acting opiate recur.[15] The patient must be carefully observed after the termination of naloxone therapy to detect any reappearance of opioid intoxication. An

IV infusion of naloxone may be appropriate if high doses are needed or if the patient has recurrent respiratory depression.

Treatment of Opioid Withdrawal Syndrome

OPIOID WITHDRAWAL

CASE 90-3

QUESTION 1: D.J. arrives at the detoxification clinic 10 hours after his last dose of heroin. He is sweating and shaking and keeps yawning. His pulse is 92 and his blood pressure is 130/86 mm Hg. He is a 28-year-old who has been injecting two "quarter bags" ($25 worth) of heroin daily for about a month. He explains he began smoking the heroin but has now progressed to injecting it. D.J. developed a "big habit" (tolerance developed, and his daily requirement of drug to maintain euphoria had increased). He could not afford his daily use. When he tried stopping, his use abruptly became "dope sick" (typical heroin withdrawal symptoms). Describe D.J.'s withdrawal symptoms and what treatment options there are available for detoxification.

Abstinence precipitated a withdrawal syndrome in D.J.; therefore, he is physically dependent on heroin. The powerful ability of the drug to rapidly alleviate withdrawal symptoms results in reinforcement to continue using the drug. D.J.'s ongoing desire to continue using heroin despite his inability to afford it and his all-day hustling constitutes a psychological dependence on heroin. Noticeable opioid physical dependence is highly variable, but it is assumed that the potential for an abstinence syndrome exists after repeated administration for only a few days.[2,18]

Six to twelve hours after the last dose of morphine or heroin (diacetylmorphine), patients physically dependent will experience symptoms of anxiety, hyperactivity, restlessness, and insomnia with yawning, sialorrhea, rhinorrhea, and lacrimation. There may also be profuse diaphoresis with concurrent shaking chills and pilomotor activity resulting in waves of gooseflesh of the skin (thus, the term cold turkey). Anorexia, nausea, vomiting, abdominal cramps, and diarrhea may occur. Severe back pain may accompany muscle spasms that cause kicking movements ("kicking the habit"). These symptoms are most severe 48 to 72 hours after the last opioid dose. D.J. is exhibiting typical heroin withdrawal symptoms, and supportive therapy would be appropriate.

During withdrawal, the heart rate and blood pressure may be elevated. Inadequate nutrition and hydration, combined with vomiting, sweating, and diarrhea, can result in marked weight loss, dehydration, ketosis, and acid–base imbalance. Rarely, cardiovascular collapse has occurred during the peak phase of opiate withdrawal. The more dramatic symptoms of heroin withdrawal subside after 7 to 14 days of abstinence even without treatment; however, a return to complete physiologic equilibrium may require months or longer.[2,3]

The character, severity, and time course of withdrawal symptoms that appear when an opioid drug is discontinued depend on many factors, including the particular opioid, total daily dose, interval between doses, duration of use, and the health and personality of the user. Unlike the withdrawal symptoms from sedative-hypnotic drugs, opioid withdrawal symptoms are seldom life-threatening.

Physiologic withdrawal symptoms from all opioid drugs are qualitatively similar but quantitatively different in onset, duration, and severity. Opioids with shorter durations of action tend to produce brief, intense abstinence syndromes, whereas those eliminated from the body at much slower rates produce prolonged but milder withdrawal syndromes.

Treatment options for detoxification usually involve either an abrupt cessation of the opioid with supportive nonopioid pharmacotherapeutic options or opioid substitution. Currently, methadone and buprenorphine are FDA-approved for the opiate substitution indications. The nonopiate approach involves symptomatic treatment of withdrawal. The mainstay of this approach is the α_2-agonist clonidine. A third approach uses rapid detoxification precipitated by an opioid antagonist under general anesthesia.[2,18]

METHADONE DETOXIFICATION

Methadone is a synthetic oral opiate agonist with a prolonged duration of action of 12 to 24 hours. Pharmacologically, it is qualitatively identical to morphine and other opioid analgesics. Methadone detoxification involves stabilizing the patient on a daily methadone dose that is determined by the patient's response based on objective symptoms of withdrawal. This may involve the use of standard rating scales for withdrawal, such as the Clinical Opiate Withdrawal Scale.[19] Initially, methadone may be given in 5-mg increments up to a total of 10 to 20 mg during the first 24 hours.[19] Larger methadone doses (i.e., a 20-mg starting dose) may be required for patients with larger habits. If initial withdrawal symptoms persist 2 to 4 hours after initial dose administration, the dose can be supplemented with an additional 5 to 10 mg. Federal regulations allow a maximum of 40 mg as an initial dose unless a program physician documents that 40 mg was insufficient to suppress opioid withdrawal symptoms.[20] Once a stabilizing dose has been reached (usually, 40–60 mg/day, but may be as high as 120 mg/day), methadone is tapered by 20% a day for inpatients or 5% a day for outpatients.[15,19,20] Studies have suggested that slow tapers are associated with better outcomes. The duration of the taper varies, but a period of 3 to 4 weeks is generally used. The gradual taper may last as long as 6 months. The most common side effects of methadone are constipation, sweating, and sexual dysfunction.[15,19] A Cochrane review of studies comparing methadone tapers with other detoxification methods (adrenergic agonists and other opioid agonists) found that programs vary widely in design, duration, and treatment objectives, but overall the effectiveness of the treatments was similar.[21] A reasonable starting dose of methadone would be 20 mg orally. An additional 5 to 10 mg could be administered after 2 to 4 hours for persistent withdrawal symptoms. The daily dose should be titrated upward every third day by 10 mg until stabilized on a methadone dose of 60 mg/day.

BUPRENORPHINE DETOXIFICATION

Buprenorphine, a synthetic partial opioid agonist, was approved by the FDA in October 2002 for the treatment of opioid dependence. It is a partial agonist at mu receptors, and in opioid-dependent patients, it prevents withdrawal symptoms. Because of its partial effects, it produces maximal "ceiling" analgesia with sublingual doses of 24 to 32 mg, a dosage equivalent to approximately 60 to 70 mg of oral methadone. Buprenorphine is associated with a milder withdrawal syndrome compared with full opioid agonists.[22]

Because buprenorphine is a schedule III medication, it can be prescribed in an office-based setting under the Drug Addiction Treatment Act of 2000. The film and tablets contain buprenorphine hydrochloride alone or in combination with naloxone. The naloxone is poorly absorbed orally, and its presence in the combination tablets is to discourage the IV abuse of buprenorphine. Both forms can be used in an inpatient setting, but the combination product is preferred in the outpatient setting to decrease the risk of diversion. When initiating buprenorphine, the first dose should not be given until more than 4 hours after the last dose of a short-acting opioid, such as heroin, or 24 hours after a long-acting opioid, such as methadone. As previously discussed, evaluation of objective opioid withdrawal signs may involve use of standard rating scales. Induction dosing should begin with 2 or 4 mg on the first day, which can be repeated every 2 to 4 hours if withdrawal symptoms subside and then reappear, up to a maximum of 8 mg. The dose can then be titrated the second day in 2- to 4-mg increments to a dose of 12 to 16 mg.[22] Higher doses during induction may precipitate withdrawal symptoms. In the inpatient setting, the patient may be stabilized on a relatively low daily dose (e.g., 8 mg/day) and then tapered in increments of 2 mg/day over the course of several days.[15] In the outpatient setting, the patient should be initially stabilized on a daily dose (probably 8–32 mg/day) of buprenorphine that suppresses withdrawal. The dose should then be gradually tapered during a period of 10 to 14 days. Buprenorphine is not associated with any significant adverse effects when used to manage opioid withdrawal. Buprenorphine (and methadone) detoxification should be accompanied by psychosocial treatments and support groups as mentioned.[3]

A Cochrane review found that relative to clonidine, buprenorphine is more effective in alleviating opioid withdrawal symptoms; patients treated with buprenorphine stay in treatment longer, and are more likely to complete treatment.[23] The severity of withdrawal appears to be similar for withdrawal managed with buprenorphine or methadone, but withdrawal symptoms may resolve more quickly with buprenorphine. The authors of the meta-analysis concluded that although there is limited evidence comparing buprenorphine with methadone, both agents have similar effectiveness in the management of opioid withdrawal.

Nonopiate Symptomatic Therapy of Opioid Withdrawal

Although opiate replacement has shown to provide a safe withdrawal, treatment with opiates is not always necessary. The ability of the α_2-adrenergic agonist, clonidine, to ameliorate some of the opioid withdrawal symptoms, has led to its widespread use as a nonopioid alternative. Other α_2-adrenergic agonists (lofexidine, guanfacine, guanabenz acetate) have also been investigated.[2,3,24] Noradrenergic outflow from the locus coeruleus is increased during opioid withdrawal and is blocked by administration of mu agonist opioids. Symptoms of opioid withdrawal, therefore, are partly caused by excessive sympathetic activity in the locus coeruleus. Central α_2-adrenergic agonists inhibit locus coeruleus noradrenergic outflow opioid withdrawal, thereby significantly reducing some of the symptoms.

Clonidine is therefore best used in a multidrug regimen. Contraindications to clonidine use include diastolic blood pressure less than 70 mm Hg, concurrent dependence on sedative-hypnotics, and clonidine hypersensitivity or previous intolerance. The most common adverse effects are sedation and hypotension. A Cochrane review examined studies comparing clonidine with methadone taper and found no significant difference in efficacy between the two for the treatment of heroin or methadone withdrawal.[24] A separate Cochrane review did find buprenorphine to be more effective than clonidine in alleviating opioid withdrawal symptoms.[23]

A sublingual or oral test dose of 0.1 mg (0.2 mg for patients >91 kg) of clonidine is given: if diastolic blood pressure remains more than 70 mm Hg, additional doses may be instituted. Oral clonidine can be used at a dose of 0.1 to 0.2 mg/dose 2 to 4 times daily to a maximum of approximately 1 mg/day for 2 to 4 days after cessation of opioids, then tapered and discontinued by 7 to 10 days.[24] Because opiate withdrawal consists of other effects such as musculoskeletal aches and pains, anxiety, insomnia, and gastrointestinal disorders, it is common to use medications such as dicyclomine, loperamide, and ibuprofen as adjuncts. This is particularly true when the detox protocol does not contain opiates.[2,18] (Table 90-2)

Table 90-2

Symptomatic Therapy of Opiate Withdrawal

Symptom	Medication
Bone, muscle, joint or other pain	Ibuprofen, naproxen, other NSAID

Insomnia, anxiety	Benzodiazepine
Gastrointestinal hyperactivity	Loperamide, dicyclomine
Nausea	Prochlorperazine, ondansetron

Sources: Schuckit MA. Treatment of opioid-use disorders. N Engl J Med. 2016;375:357–368 and ASAM Public Policy Statement on Treatment for Alcohol and Other Drug Addiction, Adopted May 1, 1980, Revised: January 1, 2010. http://www.asam.org/quality-practice/definition-of-addiction.

D.J.'s blood pressure and drug history should be evaluated for clonidine therapy. Provided his diastolic blood pressure is greater than 70 mm Hg after the clonidine test dose, he can receive oral clonidine 0.1 mg with additional medications to treat his withdrawal symptoms, along with psychosocial counseling.

Ultrarapid Opiate Detoxification

Ultrarapid opiate detoxification (UROD) is a method to shorten the opioid detoxification period by precipitating withdrawal with an opioid antagonist. The opioid antagonist causes rapid stripping of agonist from opioid receptors. UROD is performed under heavy sedation or general anesthesia so the patient does not consciously experience the acute withdrawal symptoms. The protocols for UROD vary in terms of the setting of the procedure (inpatient or outpatient), opioid antagonist (naloxone, nalmefene, or naltrexone), anesthetic agent, adjunctive medications, and duration of anesthesia.[25]

The UROD procedure includes risks, such as vomiting with aspiration; cardiovascular complications, including cardiac arrest; pulmonary edema; and death.[25] Some patients have reported residual withdrawal symptoms for several days. Little information exists regarding referral to ongoing treatment or relapse rates after UROD.[26] A review of five randomized, controlled trials found no benefit of UROD compared with safer, less expensive treatments.[26] UROD has been criticized for being simply a "quick fix" that fails to address the underlying behavior changes necessary for recovery. Additionally, it subjects patients to possible morbidity and mortality when safer, established procedures are available. The high cost of UROD limits its accessibility. The American Society of Addiction Medicine recommends against this method of treating opiate withdrawal due to cardiac complications and anesthesia related events.[2]

Pharmacotherapies for maintenance treatment of Opioid Use Disorder

MAINTENANCE THERAPY

The ultimate goal of outpatient substance use disorder programs is to assist the addicted patient into a drug-free healthy lifestyle. This results in reductions in medical conditions for the patient and reduced crime and health care cost for societal members. Methadone for maintenance treatment of opioid substance use disorder is federally regulated and is only available through specially licensed opioid treatment programs. The Drug Addiction Treatment Act of 2000 allows qualified physicians to prescribe Schedule III, IV, and V medications approved for the treatment of opioid dependence in an office-based setting.[27] Currently, only buprenorphine, a Schedule III medication, is approved for this indication.

CASE 90-4

QUESTION 1: A.X., a 27-year-old man, has a severe opiate use disorder (addiction) to heroin for the last 3 years but is tired of the street scene and wants to "get clean" (complete abstinence). He can no longer afford his growing daily habit but is not sure he can stop using opioids. He seems willing and determined to receive treatment for his heroin dependence. What therapeutic options are available to him?

The goal of eliminating illicit opiate use is the gold standard; however, a more realistic expectation is reduced use and subsequent harm reduction. Even temporary reductions in heroin use are a benefit due to reduced risk of developing major health (HIV, hepatitis C) and social (crime) issues.[2] Medical management of opioid dependence should be accompanied by psychosocial treatments, such as cognitive-behavioral therapies, behavioral therapies, and self-help groups, such as Narcotics Anonymous (NA).

Methadone maintenance is the most common form of pharmacologic treatment for opioid dependence. During methadone maintenance, heroin-dependent patients are stabilized on a dose of methadone that will be sufficient to suppress cravings for 12 to 24 hours without producing euphoria. Studies have shown that patients maintained on methadone doses of 60 mg or more had better outcomes than those maintained on lower doses.[28] Most patients do well on a dose range of 60 to 120 mg/day, although some patients require more and some require less.[20] Because methadone is metabolized via CYP450 3A4 drugs that induce, this pathway can precipitate withdrawal in patients maintained on methadone. Drugs that inhibit this pathway extend the duration of methadone's effects. The half-life of methadone is typically 25 hours (15–60) but can extend up to 120 hours with frequent dosing.[29] The drug is administered daily at the clinic in a single liquid oral dose. With the aid of daily counseling and rehabilitation, the goal is to eventually taper the patient from methadone as well. Patients who relapse repeatedly despite supportive treatment will require long-term maintenance therapy. This may take years, and it is shown that longer duration in treatment correlates with better outcomes. Methadone's efficacy comes from the fact that it reduces cravings without producing euphoria itself, primarily due to its slow time to peak. This produces a high degree of cross-tolerance to other opioids so that it is extremely difficult to obtain euphoria with IV injection of other opioids. But, patients have been able to reach euphoric states through the concomitant IV administration of other opioids. The higher purity heroin available today has required even higher doses of methadone to achieve cross-tolerance.[28] It is often cut (mixed) with fentanyl to increase the opiate effect.

Buprenorphine has the advantage of office-based availability, thus removing the stigma associated with attending a methadone clinic and providing more places for patients to receive treatment because methadone clinics are limited as to how many patients can enroll and may be hundreds of miles away from the patient's home. Buprenorphine, and high-dose methadone (60–100 mg) therapies were compared with low-dose methadone (20 mg), all three therapies were effective in treating opioid dependence and were superior to low-dose methadone.[30] Trials comparing 12 to 16 mg/day of buprenorphine with moderate doses of methadone (50–60 mg/day) have generally shown comparable outcomes, although higher doses of methadone (>80 mg) appear to be superior to buprenorphine.[30] Low-dose buprenorphine seems to have worse outcomes compared to low-dose methadone.[31] Buprenorphine patients are more likely to be employed, have less medical comorbidity, and a shorter duration of drug use compared to methadone clinic patients.[32,33] There are multiple formulations of buccal and sublingual buprenorphine and absorption rates are different between some of them. All are compared to the original buprenorphine sublingual tablet (Subutex and Suboxone) regarding pharmacokinetics, blood levels and efficacy. There is also a buprenorphine implant available which was found similarly effective to lower doses of buprenorphine sublingual.[34] For maintenance treatment buprenorphine combined with naloxone is the standard of care with pregnancy or allergy to naloxone the only two reasons not to use the combination.[2]

Buprenorphine has a long half-life of around 35 hours (24–60 hours) and it produces a relatively mild withdrawal when discontinued.[35] It is believed to be a safer alternative to methadone because life-threatening respiratory depression is much less likely to occur than with a pure mu agonist, unless another CNS depressant is taken concurrently. Most deaths involving buprenorphine have been caused by a combination of the drug with benzodiazepines and through injection of the monotherapy formulation.[22,36] Naloxone bolus doses often are ineffective in reversing respiratory depression caused by buprenorphine because of its prolonged occupancy on mu receptors. Continuous infusion of naloxone is necessary to overcome buprenorphine-induced respiratory depression.[37] Another safety advantage compared to methadone is the lower risk of prolonging QTc.[29] Similar to methadone, buprenorphine is also metabolized by CYP450 3A4.

The narcotic antagonist naltrexone can block the euphoriant effects of heroin and other opiates, prevent the development of physical dependence, and afford protection from opioid overdose deaths. Although naloxone is similar to naltrexone, it is impractical because of its short duration of action and its extremely poor absorption when taken orally. Naltrexone is orally active and provides a dose-related duration of opioid blockade. An oral dose of 100 mg of naltrexone will block opiate effects for 2 days, and 150 mg for 3 days. Thus, dosing on Monday, Wednesday, and Friday is possible; however, it is recommended to use 50 mg QAM because it is easier to remember for the patient and will result in better adherence. Naltrexone is also available in an injectable extended-release formulation for once-monthly use.[38] Patients selected for naltrexone therapy must be opioid free to avoid precipitation of withdrawal. For heroin- or morphine-dependent patients, a 4- to 7-day wait is recommended, whereas longer half-life opiates can require a 10- to 14-day wait. Patients who are highly motivated to abstain have been most successfully treated with this drug.

Because A.X. has had a short duration of opiate misuse, he is a good candidate for outpatient buprenorphine/naloxone or naltrexone. Methadone is equally effective but does require enrollment into a clinic, which may or may not be practical for him. Methadone clinics are considered more effective than the other choices because the addiction becomes more severe.

Research suggests that physicians consume more opioids, sedatives, and alcohol than the general public, but less tobacco.[39] The risk is largely based on access to drugs of abuse, and drug dependence is described as an occupational hazard for healthcare providers. Fentanyl (injectable as well as transdermal formulations) and meperidine are primarily, but not exclusively, drugs of abuse among health care providers. Hospice workers and veterinarians also have access to high-potency opioids. Studies have noted that substance use was highest in psychiatrists and emergency medicine physicians and lowest in surgeons and pediatricians.[39] Fentanyl is associated with rapid development of dependence, intense tolerance, and drug-seeking behavior in addicted physicians for a period of months rather than years.

A comprehensive assessment of addicted health care providers is necessary to determine whether professional impairment is present, and whether issues involving public health and safety or violations of ethical standards, such as professional boundary violations or improprieties, require that the heath care provider be reported to his or her respective medical board. A physician’s registration with the federal DEA may need to be suspended. It generally is accepted that health care providers require longer durations of treatment because they are held to a higher standard of recovery owing to concerns of public safety, and they may be clever at concealing their illness.[39]

Health care providers are often good candidates for naltrexone therapy (particularly the long action injection) because of the need to remain drug-free despite continued access to opioids at work.

Opiate Use Disorder Treatment in Pregnancy

CASE 90-5

QUESTION 1: J.R., a 28-year-old woman, has been maintained on 100 mg of methadone daily for the past year. J.R.'s last menstrual period was 8 weeks ago, and she took a home pregnancy test yesterday, which was positive. What is the recommend treatment for pregnant patients?

Methadone has been accepted since the late 1970s to treat opioid use disorder during pregnancy.[20] Methadone maintenance was determined to be the standard of care for pregnant women with opioid use disorder by a 1998 National Institutes of Health (NIH) consensus panel.[40] Currently, methadone is the only opioid medication approved by the FDA for medication-assisted treatment of opioid use disorder in pregnant patients. Women maintained on methadone frequently have regular menstrual periods, ovulate, conceive, and have normal pregnancies. Heroin-addicted mothers, however, generally experience more complicated pregnancies because their lifestyles often predispose them to a poor general state of health and precludes adequate prenatal medical care.[22] Infants born to heroin-addicted mothers may also be exposed to other substances (e.g., alcohol, cocaine, tobacco). These infants tend to be smaller, to weigh less at birth, and to be born prematurely compared with the children of women not using opiates.[22]

WITHDRAWAL DURING PREGNANCY

J.R. should continue methadone maintenance to avoid precipitating a withdrawal syndrome or a relapse to opiate addiction. Both relapse and withdrawal syndrome could lead to a spontaneous abortion.[20] A structured methadone maintenance program provides access to counseling and perinatal medical care which are additional benefits. The dose of methadone should be titrated individually throughout the pregnancy and may even need to be increased and switched from QD to BID dosing due to changes in kinetics that occur during pregnancy.[2] The neonate can be managed for either opioid-induced CNS depression or methadone withdrawal after delivery, as needed.

Methadone continues to be the standard of care for the management of opioid dependence in pregnancy; however, a growing body of evidence suggests buprenorphine may be a reasonably safe alternative.[15] Also most evidence suggests that infants born to buprenorphine-maintained women have a lower incidence of neonatal abstinence syndrome and shorter hospital stays.[41–43]

NEONATAL ABSTINENCE SYNDROME (NAS)

CASE 90-5, QUESTION 2: Because methadone crosses the placental barrier, will J.R.'s infant exhibit opioid withdrawal symptoms after birth, and if so, how should they be managed?

Methadone crosses the placental barrier and can cause CNS and respiratory depression as well as opioid withdrawal in the newborn. In general, the most common opioid NAS symptoms include restlessness, tremors, a high-pitched cry, hypertonicity, increased reflexes, regurgitation, tachypnea, diarrhea, and sneezing. Seizures are associated with, but not necessarily caused directly by, opioid withdrawal in the neonate.[44]

Management of the neonate's opioid withdrawal syndrome entails careful attention to hydration with demand feeding and symptomatic care. Treatment of opioid NAS should begin when symptoms occur; prophylactic therapy is not recommended. Mild withdrawal symptoms generally do not need therapy, but moderate to severe symptoms may require 14 or more days of treatment.[44]

Symptoms of physiologic withdrawal are usually apparent within 48 hours of birth. At this time, treatment can be initiated. Currently, NAS is treated with morphine.[41,44–46] Morphine can be started at a dose of 50 mcg/kg given orally four times daily and titrated to control symptoms. Once the NAS symptoms have stabilized, the dose can be decreased daily by 20% until discontinuation of the drug. Phenobarbital is preferred for the treatment of NAS in cases of combined dependence or benzodiazepine dependence or if maximum doses of opiate have been used.[41] If used, phenobarbital is instituted in doses of 5 to 10 mg/kg/day in the first 24 hours, then tapered symptomatically, usually about 20%/day.

If J.R.'s infant displays opioid withdrawal symptoms (e.g., feeds poorly, becomes tremulous or agitated), morphine at a dosage of 50 mcg/kg orally given four times daily would be an appropriate intervention. This dosage is given until symptoms stabilize and then gradually tapered (e.g., 20% each day) during the next week. Buprenorphine has also shown positive data supporting its use and is a potential option if morphine is unacceptable.[44]

BREAST-FEEDING

Methadone is excreted into the breast milk of methadone-maintained mothers. The amount of methadone in the breast milk is unlikely, however, to have adverse effects on the infant.[47] Furthermore, studies have found minimal transfer of methadone into breast milk.[20] There are little data regarding the safety of buprenorphine in breast-feeding. One study found low levels of buprenorphine and its active metabolite, nalbuphine, in infants' urine.[48] Breast milk offers advantages clearly beneficial to infants, and J.R. should be encouraged to breast-feed her infant.

SEDATIVE-HYPNOTICS (NON-ETOH)

The sedative-hypnotics are a diverse group of compounds with broad clinical uses, including anesthesia, treatment of anxiety, and treatment of insomnia. Ethanol, also a sedative-hypnotic agent, continues to be the most widely abused substance in the United States and will be discussed later. Benzodiazepines have become the prototypical sedative-hypnotic drugs of abuse. Other abused sedative-hypnotic drugs include carisoprodol and γ-hydroxybutyric acid (GHB). Carisoprodol, a nonscheduled skeletal muscle relaxant, has an active metabolite meprobamate, a sedative-hypnotic agent with known abuse potential.[49] GHB is a putative neurotransmitter abused for its euphoric and sedative-hypnotic effects. Although sedative-hypnotics can be abused as monotherapy, they are more commonly used as adjuncts to other chemicals such as opiates and EtOH.

Abstinence Syndromes Associated with Sedative-Hypnotic Dependence

CASE 90-6

QUESTION 1: During a year of therapy for anxiety, B.J. increased his dose of alprazolam to two 1-mg tablets 5 times a day. He has admitted to "doctor shopping" and buying alprazolam on the street. He states he uses the benzodiazepine to get high but he also becomes extremely anxious if he doesn't use any alprazolam for more than an afternoon. Will he experience withdrawal symptoms if he suddenly discontinues alprazolam?

Patients who have been on long-term courses of therapeutic doses of sedative-hypnotics often experience withdrawal symptoms on abrupt discontinuation of therapy. Withdrawal syndromes seen with sedative-hypnotics are similar to those seen with alcohol withdrawal and can include insomnia, anxiety, tremors, headaches, restlessness, nausea, vomiting, hypertension, tachycardia, hypersensitivity to light, sound, and touch, and perceptual distortions.[50] Generalized tonic–clonic seizures can occur as isolated seizures or as status epilepticus. The psychoses that develop resemble the delirium tremens produced by alcohol withdrawal and are usually characterized by disorientation, agitation, delusions, and hallucinations. During the delirium, hyperthermia and agitation can lead to exhaustion, rhabdomyolysis, cardiovascular collapse, and death. Abstinence from short-acting barbiturates and meprobamate produces symptoms that peak within 1 to 5 days. Discontinuation of short-acting benzodiazepines (e.g., lorazepam, oxazepam, alprazolam, temazepam) results in the abrupt onset of withdrawal symptoms, usually within 12 to 24 hours after the last dose. Long-acting agents, and those with active metabolites, have a gradual onset of milder withdrawal symptoms compared with the short-acting agents. Withdrawal symptoms after chronic use of long-acting benzodiazepines typically occur within 5 days of cessation and peak at 1 to 9 days after the last dose.[50]

B.J. has been abusing alprazolam, taking more than the recommended maximal dose. Likely, he will experience withdrawal, possibly including seizures, if he were to abruptly discontinue the alprazolam. His withdrawal from this medication should be medically managed.

Treatment of Sedative Withdrawal

Three general medication strategies are used for withdrawing patients from sedative-hypnotics: tapering; substituting (and gradual taper) of phenobarbital for the drug of dependence; and the substituting (and gradual taper) of a long-acting benzodiazepine for the drug of dependence.[51] Gradual tapering of the drug of dependence is appropriate for patients with therapeutic dose dependence or those taking long-acting sedative-hypnotics, who are not currently abusing alcohol or other substances. A recent meta-analysis suggests that management of benzodiazepine mono-dependence by gradual taper is preferable to abrupt discontinuation.[52] The patient who is abusing sedative-hypnotics already has a strong association between the drug of choice and certain desired effects. Therefore, to minimize exacerbating addictive disease, substitution and taper with a long-acting therapeutic agent is preferred.

The phenobarbital method is used in some drug treatment programs. The pharmacologic rationale for phenobarbital substitution is that it is long acting, producing little changes in serum levels between doses, thereby preventing breakthrough withdrawal symptoms. Lethal doses are many times higher than toxic doses, and dysphoria occurs with elevated dose, rendering it less desirable for abusers.

The standard method involves calculating a phenobarbital replacement dose for the total daily dose of the sedative-hypnotic being abused. The calculation is based on phenobarbital equivalents (Table 90-3). If multiple sedative-hypnotics are being used, the totals for each drug and alcohol (amount of pure ethanol) are summated. The total phenobarbital substitution dose should be given in divided doses, 3 or 4 times daily (to avoid dysphoria). Because the calculated dosage is an estimate based on patient history, which may be inaccurate, it is advisable to administer a test dose if the calculated replacement dose is more than 180 mg/day. The test dose, generally one-third the total dose, is given to the patient, who is then observed for 1 to 2 hours. The patient is observed for mitigation of withdrawal symptoms as well as signs of overmedication, such as somnolence or incoordination. Once an appropriate dose is determined, the patient is usually stabilized on that dose for 1 to 2 weeks. After stabilization, a gradual taper of phenobarbital is instituted, with dosages reduced by 15 mg weekly or every other week, or 10% of the current (starting) dose per week. For the last 25% to 35% of the taper, the rate is slowed to keep the patient stabilized. The taper should be held for a few days if withdrawal symptoms occur.[50]

Table 90-3

Hypnotic Dose Equivalent to 30-mg Phenobarbital

Pure ethanol 30–60 mL	Clonazepam 1–2 mg	Pentobarbital 100 mg
Alprazolam 0.5–1 mg	Diazepam 10 mg	Secobarbital 100 mg
Butalbital 100 mg	Flunitrazepam 1–2 mg[a]	Temazepam 15 mg
Carisoprodol 700 mg	Lorazepam 2 mg	Triazolam 0.25–0.5 mg
Chlordiazepoxide 25 mg	Oxazepam 10–15 mg	Zolpidem 5 mg

[a] Not approved for use in the United States.

Source: Dickinson WE, Eickelberg SJ. Management of sedative-hypnotic intoxication and withdrawal. In: Ries RK et al. eds. Principles of Addiction Medicine, 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2009:573.

B.J. has a substance use disorder to alprazolam. Tapering of alprazolam or conversion to phenobarbital will both result in a safe withdrawal. His total dose of alprazolam is 10 mg/day, so if phenobarbital is used he should receive 300 mg divided 3 or 4 times a day. The total daily phenobarbital dose or alprazolam dose should be tapered by 10% of the dose per week as tolerated.

γ-Hydroxybutyric Acid

γ-Hydroxybutyric acid (GHB), commonly referred to as “liquid ecstasy,” is a potent “club drug.” Once available as an over-the-counter nutritional supplement, primarily used by bodybuilders for its muscle building effect, the FDA removed it from the retail market in 1990 because of widespread reports of poisoning. In 2000, it was classified as a schedule I drug; however, a GHB-containing product, sodium oxybate, is available as a schedule III prescription drug for the treatment of cataplexy associated with narcolepsy. GHB is found in mammalian brain tissue, where it is derived from conversion of its parent neurotransmitter, γ-aminobutyric acid (GABA).[53] It is believed to be a neurotransmitter. Experimental evidence suggests that the mechanism of action of exogenously administered GHB involves agonist activity at the $GABA_B$ receptor.[53]

γ-Hydroxybutyric acid has CNS depressant effects and is abused for its euphorigenic properties, disinhibition, and enhanced sensuality. Its psychic effects are similar to those of alcohol, and include increased libido, short-term anterograde amnesia, and a dreamy, altered sensorium. It has a steep dose-response curve, and common adverse effects include dizziness, nausea, weakness, agitation, hallucinations, seizures, respiratory depression, and coma. Its effects are synergistic with alcohol. GHB overdose may be fatal, and there is no antidote. Treatment for GHB overdose is primarily supportive.

Highly addictive, tolerance and physical dependence can occur with regular use of GHB, and a withdrawal syndrome has been seen in people who have taken high doses of it (~18 g/day or more, although doses are variable in solution form) with frequent dosing (every 1–3 hours).[53] Withdrawal symptoms can include muscle cramps, nausea, vomiting, tremor, anxiety, insomnia, tachycardia, restlessness, and delirium or frank psychosis. Death caused by pulmonary edema has been reported. Treatment of withdrawal involves supportive care, including use of benzodiazepines (e.g., lorazepam or diazepam) for sedation. Withdrawal can last up to 2 weeks.[53]

Misrepresented sometimes as a natural and safe hypnotic, the low therapeutic index and the unknown purity of illicit supplies, particularly when sold in solution, make GHB a potentially dangerous drug. Physical dependency is a possibility as well. GHB, along with the benzodiazepine flunitrazepam, are considered "date rape" drugs because they cause profound hypnosis and amnesia. This is intensified when mixed with alcohol which is often how the sexual predator gives it to his victim.

CENTRAL NERVOUS SYSTEM STIMULANTS

Cocaine

Cocaine is a naturally occurring alkaloid derived from the Erythroxylon coca plant, found mainly in the Andes Mountains of South America. Cocaine was first isolated in the 1800s and was a common ingredient in tonics and elixirs of the 1900s. The Harrison Narcotic Act of 1914 prohibited nonmedical use, and in 1970 it became a schedule II controlled substance. According to the 2014 National Survey on Drug Use and Health, nearly 1 million people in the continental United States have a diagnosed cocaine use disorder within the last year which is similar to the rate in 2009.[4] Cocaine is a CNS stimulant and has vasoconstrictive and local anesthetic properties. Cocaine's stimulant effects are primarily caused by blockade of the reuptake of dopamine, norepinephrine, with a small effect on serotonin. It also facilitates the release of dopamine and norepinephrine. This results in an overall increase in availability of neurotransmitters. Cocaine also has other indirect effects on neurophysiology, including effects on the endogenous opioid systems.[54,55] Cocaine is associated with compulsive use. The powerful reinforcing effects of cocaine have been identified as occurring in brain regions rich in dopaminergic nerve terminals.

DOSAGE FORMS AND ROUTES OF ADMINISTRATION

In the manufacture of cocaine, organic solvents are used to solubilize the alkaloidal bases from the leaves, which are then precipitated to form a sticky material, called "pasta" or "cocaine paste." The benzoylmethylecgonine (cocaine) in this "pasta" is separated from most of the other plant alkaloids, converted to the hydrochloride or other salts, precipitated, and dried. This product is the white cocaine hydrochloride powder usually seen in the illicit market. The final product is usually "stepped on" or "cut" (diluted) with various adulterants to increase profits for the dealers. According to the DEA, in 2009 the average purity of cocaine was down from 68.1% in 2006 to

46.2%.[56] Powdered cocaine is generally snorted. Usually 10 to 25 mg of powdered cocaine is placed on a mirror or flat surface, formed into a line, and then insufflated through a straw or rolled dollar bill. A typical low to moderate user may consume 1 to 3 g/week. Cocaine powder can also be used for IV injection. The highly water-soluble powder is usually mixed with water and injected. When cocaine is injected simultaneously with heroin, this is known as a “speedball.”

Cocaine hydrochloride melts at a high temperature, destroying much of its psychoactivity in the process. Therefore, it is inefficient to smoke cocaine hydrochloride in this form. The use of “freebase” cocaine became popular during the late 1970s, because this form of cocaine has a lower melting point and can therefore

be smoked, producing an intense rush. For freebase, the cocaine hydrochloride is dissolved into ethyl ether. The synthesis of freebase is dangerous, and the resultant product may contain residual organic solvents, thus making it highly volatile and putting the user at risk of burns.

In the mid-1980s a safer, easier method for extracting the cocaine base supplanted the traditional freebase process. In the manufacture of “crack,” cocaine hydrochloride is dissolved in water. When alkali (bleach or sodium bicarbonate) is added to this aqueous solution, the free alkaloidal base (“crack”) precipitates out whereas the salts and some adulterants stay in aqueous solution. The precipitate is commonly referred to as a “rock.” The size of the rock varies but generally ranges from one-tenth of a gram to a half a gram.

PHARMACOKINETICS AND EFFECTS

Cocaine generally produces a euphoriant action with a rapid onset and short duration. Snorting cocaine generally produces euphoria and stimulation within 2 minutes; smoking produces these effects within 6 to 8 seconds. Cocaine has a short elimination half-life of approximately 30 minutes owing to its rapid metabolism by esterases in the plasma, liver, brain, and other tissues.[54] When alcohol and cocaine are consumed together, a metabolite, cocaethylene, is formed. Cocaethylene intensifies the euphoric as well as the toxic effects of cocaine. The risk of death from cocaethylene is 18 to 25 times greater than with cocaine alone.[56]

An initial relaxed, euphoric, gregarious, talkative, hyperactive state characterizes the “high” of cocaine. Additionally, the person may report increased interest in sexual matters, diminished short-term memory, periods of intense concentration on one limited subject, diminished hunger, hypervigilance, and a peculiar, slightly out-of-body sense of one’s actions. Without additional doses of cocaine, these feelings usually resolve into a state of mild depression, fatigue, hunger, and sleepiness by 1 to 3 hours. Physiologic manifestations include mydriasis, sinus tachycardia, vasoconstriction with hypertension, bruxism, repetitive behavior, hyperthermia, and talkativeness. After a few hours, continuous self-administration of cocaine will begin to progress from euphoria to dysphoria and hallucinosis and then to psychosis. Some users engage in nonstop binges of self-administration until psychological toxicity develops.[57]

ADVERSE EFFECTS

In 2007, 553,530 cocaine-related visits to an emergency department were reported in the United States.[58] The potential adverse effects associated with both acute and chronic use of cocaine are numerous and involve most organ systems in the body.

The cardiac complications associated with cocaine use include hypertension, arrhythmias, myocardial ischemia and infarction, dilated and hypertrophic cardiomyopathy, myocarditis, aortic dissection, and acceleration of atherosclerosis. These cardiac effects have occurred in individuals with and without underlying heart disease who have taken large or small doses by all routes of administration and may be associated with acute or chronic use. The cardiac events can occur before, during, or after other toxicities, such as seizures, and can be fatal. The mechanism of cocaine-induced myocardial infarction is most likely multifactorial, involving one or more of the following processes: coronary artery vasoconstriction, increased myocardial oxygen demand related to increased blood pressure and increased heart rate, increased platelet aggregation and thrombus formation, coronary vasospasm, and arrhythmia. The risk is greatest within the first hour after use.[59] Studies have shown 6% of patients presenting to emergency departments with chest pain after cocaine use have myocardial infarctions.[56,57,59]

The medical management of acute coronary syndromes differs when cocaine is the cause. Specifically, nonselective β-blocker therapy (i.e., propranolol) is contraindicated due to unopposed alpha affects, thrombolysis should be used with caution, and nitroglycerine and benzodiazepines are part of first-line therapy.[56,57,59] In patients with cocaine-associated chest pain, a 12-hour observation period to rule out myocardial infarction or ischemia is probably sufficient before discharge from a medical facility.[57]

Cocaine has also been associated with cerebrovascular catastrophes. Stroke can occur as a result of increased blood pressure, vasoconstriction, or thrombosis. Seizures are another CNS complication. Seizures can occur with first use and are most often single, generalized tonic–clonic seizures. Most occur within 90 minutes of drug use, when drug plasma concentrations are highest.[54]

The route of cocaine administration also affects the nature of the adverse effects. For example, pulmonary complications, including pneumomediastinum, pneumothorax, pneumopericardium, acute exacerbation of asthma, diffuse alveolar hemorrhage, pulmonary edema, and “crack lung,” are associated with smoking crack cocaine. Crack lung is a syndrome of acute pulmonary infiltrates associated with a spectrum of clinical and histologic findings.[56] Snorting cocaine can lead to perforation of the nasal septum because of the drug's local anesthetic and vasoconstrictive effects. IV use of cocaine has been associated with renal infarction, wound botulism, viral hepatitis, HIV infection, bacterial endocarditis, sepsis, and other infectious complications.

COCAINE USE DISORDER

A person who uses cocaine despite adverse consequences (emergency department visit), uses it compulsively, suffers withdrawal symptoms, and alleviates symptoms with further use is diagnosed with cocaine use disorder per the DSM-5. Prolonged or heavy use of cocaine has been associated with the development of tolerance to some of its central effects. Tolerance is caused by adaptive changes in the brain.[54] A withdrawal syndrome may follow long-term or binge use. The initial, acute symptoms, referred to as the "crash," consist of depression, fatigue, craving, hypersomnolence, and anxiety. Anhedonia and hyperphagia soon follow. Although most symptoms are mild and resolve within 1 to 2 weeks, the dysphoria and anhedonia can persist for weeks. These symptoms do not produce profound physiologic changes and are generally not life-threatening.[57]

TREATMENT OF COCAINE USE DISORDER

Most cases of simple cocaine withdrawal do not require medical treatment. However, multiple pharmacologic therapies to facilitate abstinence from cocaine have been, and continue to be, under investigation. Most studies have yielded variable results, and to date no drug exists that is proven effective in treating cocaine dependence.[15] Studies of dopamine agonists (amantadine, selegiline, levodopa/carbidopa, pergolide), antidepressants (desipramine, fluoxetine, bupropion), and carbamazepine have yielded inconsistent findings. Methylphenidate has been investigated as "maintenance treatment" to satisfy the cocaine addict's desire for further enhancement of mood; however, methylphenidate also can stimulate a powerful craving for the more intense euphoria of cocaine and has significant abuse potential. Recent research shows promise for topiramate, baclofen, tiagabine, and modafinil, but these findings require replication.[15] A cocaine vaccine is currently under investigation. Psychosocial treatments focusing on abstinence have been effective in the treatment of cocaine dependence.[15] Cognitive-behavioral therapies and behavioral therapies, such as contingency management, along with 12-step–oriented individual counseling can be useful, although the efficacy of these therapies varies. Participation in a 12-step self-help group (AA, NA), as an adjunct to treatment, seems to predict less cocaine use.[3,15]

Amphetamines

Central nervous system stimulants have been used both with and without social acceptance for thousands of years. The Chinese prepared ephedrine-containing products from a plant called Ma-Huang (Ephedra vulgaris).[7] People in East Africa and the Arabian Peninsula chew the leaves of the khat bush (Catha edulis) for the stimulating effects of the alkaloid cathinone.[54] Caffeine is consumed worldwide in a usually socially acceptable manner in the form of coffee and energy drinks. Amphetamine was synthesized in 1887, and methamphetamine in 1919. The legal sanctions against widespread prescribing of amphetamines in the 1970s restricted their supply and fostered a black market thriving on the illicit production of methamphetamine powder ("speed," "meth," "crank," "crystal meth"). During the 1990s, California and the West Coast experienced a dramatic resurgence of methamphetamine-related hospital admissions, poison center calls, and law enforcement actions. Methamphetamine misuse has since become a nationwide problem, prompting government restrictions on retail sales of ephedrine and pseudoephedrine (precursor chemicals used in the manufacture of methamphetamine). A new marketing tool developed by savvy drug dealers aimed at younger, new users involves bright coloring and flavoring (strawberry, cola, cherry, orange) added to crystal methamphetamine to help mask the bitter taste. According to the National Survey on Drug Use and Health for 2014, there were 569,000 current users of methamphetamine in America.[4]

PHYSICAL AND PSYCHOLOGICAL EFFECTS

CASE 90-7

QUESTION 1: D.C., a college student, used amphetamine this past weekend when partying with his friends. He has a midterm examination in 2 days and is too tired to study, so one of his friends suggests snorting some more amphetamine and then hitting the books. D.C. finds amphetamine very much to his liking and begins to use it daily. He goes many days at a time without sleeping or showering and starts losing weight because he seldom has an appetite. He believes his friends are working with the DEA and tapping his phone. Are these symptoms of a stimulant use disorder?

Methamphetamine produces CNS stimulation by enhancing the effects of norepinephrine, serotonin, and dopamine. This is accomplished by both blocking the reuptake and stimulating release of these neurotransmitters. These effects are greater for dopamine and norepinephrine than for serotonin.[47]

The powerful stimulating effects of amphetamine and methamphetamine have made their use popular among a wide variety of groups, including students, athletes, the military, dieters, and long-distance truck drivers. Initially, the user may experience alertness, euphoria, increased energy, the illusion of increased productivity, sociability, and decreased appetite. Continuous dosing, however, produces stereotypical grooming and other repetitive motions. Physiologic effects include bruxism, tremor, muscle twitching, mydriasis, hypertension, diaphoresis, elevated body temperature, nausea, dry mouth, weight loss, and malnutrition. Continued use for several days decreases productivity and is associated with disordered thoughts, paranoia, and psychosis. Tolerance develops very rapidly after continued use.[54]

Illicit methamphetamine is commonly insufflated or injected and, less commonly, taken orally. In a pattern similar to that seen with smoking cocaine, users freebase methamphetamine and smoke it. Heating the crystals and smoking the vapor of "crystal meth," as with crack, is a common route of administration; however, snorting and IV administration are also used. Absorption is rapid after smoking, and the effects can last as long as 24 hours. Methamphetamine-induced psychosis may occur more frequently with smoking.

D.C. will probably be able to stay awake to study if he uses more methamphetamine; however, if he is up for too many days without sleep, his performance on the examination will suffer.

ADVERSE EFFECTS AND TOXICITIES

D.C. is exhibiting classic signs of chronic methamphetamine abuse, which will likely progress if he continues using. A "speed freak" or "tweaker" (chronic methamphetamine user) is generally regarded even by other drug users as mentally unstable, aggressive, and emotionally labile, with unpredictable periods of violent, even homicidal, behavior. Chronic users characteristically develop complex paranoid delusional systems with hallucinations during extended periods of intoxication that may involve several sleepless days and nights of continuous methamphetamine administration. This "speed psychosis" may include tactile hallucinations, such as formication (the sensation of something crawling under the skin). The initial treatment approach for stimulant-induced adverse psychologic effects is nonpharmacologic. The distressed patient may be calmed by reducing environmental stimuli and using the "ART" approach developed by the Haight-Ashbury Free Clinic in San Francisco: **A**cceptance of the patient's immediate needs; calm **R**eassurance that the condition is caused by the drug and will resolve eventually; and **T**alk-down, which involves reassuring, reality-oriented communication.[57] An extremely agitated, anxious, psychotic user, however, will often require administration of a benzodiazepine, such as diazepam (10 to 30 mg orally or 2 to 10 mg intramuscularly or intravenously) or lorazepam (2 to 4 mg orally, intramuscularly, or intravenously). If psychosis persists, a high-potency neuroleptic, such as haloperidol (5 to 10 mg orally, intramuscularly, or intravenously) or risperidone (2 to 4 mg orally), is preferred owing to its minimal anticholinergic activity. Low-potency neuroleptics, such as chlorpromazine, with higher anticholinergic activity, may worsen symptoms of delirium and hyperthermia.[57]

The physiologic toxicity of stimulant drugs includes hypertension, stroke, seizures, hyperthermia, sexual dysfunction, dental caries, rhabdomyolysis, renal failure, cardiac arrhythmias and cardiomyopathies, myocardial infarction, and malnutrition.

The development of neurotoxicities involving dopaminergic and serotonergic neurons (possibly through interference with monoamine transport and increased production of reactive oxygen species) has been demonstrated in animals. It also appears to cause permanent neuronal toxicity with prolonged use.[60]

WITHDRAWAL AND TREATMENT

CASE 90-7, QUESTION 2: D.C. is arrested for assault after a bar fight. He is held in the county jail and is unable to post bail. What withdrawal symptoms might he experience during incarceration?

D.C. will probably suffer intense cravings for methamphetamine and initial agitation, followed by fatigue and hypersomnolence. A withdrawal state after acute cessation of chronic stimulant use is generally the same as that previously described for cocaine. As with cocaine, the crash is notable for marked fatigue, depression, and anhedonia. Most symptoms are mild and will resolve within 1 to 2 weeks, although anhedonia and depression may persist.

Clinical studies investigating treatments for methamphetamine dependence is similar to cocaine treatments. Currently, no pharmacologic treatments have been proved effective for methamphetamine dependence. The most effective treatment so far appears to be psychosocial therapies, such as cognitive-behavioral therapy and contingency management.[57]

DISSOCIATIVE DRUGS: PHENCYCLIDINE, KETAMINE, AND DEXTROMETHORPHAN

Phencyclidine (phenylcyclohexylpiperidine) and ketamine are arylcycloalkylamine, dissociative, anesthetic agents. Phencyclidine (PCP) at one time was marketed as an IV anesthetic agent under the trade name of Sernyl.[61] Subsequent reports of postanesthetic dysphoric reactions caused the drug to be withdrawn in 1965. It was reintroduced in 1967 as Sernylan and marketed as a veterinary anesthetic until 1978, when the manufacture and sale of the drug became illegal. Ketamine is currently used clinically as an anesthetic in both animals and humans. There is some data supporting its use in treatment refractory depression but common side effect of dissociation has confounded the blinding of studies and is a significant side effect. More research is necessary but it is possible that it could be used for very short-term treatment during the efficacy lag of established antidepressants.[62] Ketamine is shorter acting and somewhat less potent than PCP.

Abuse of arylcycloalkylamines occurs primarily in large metropolitan areas. PCP is relatively easy to synthesize and is inexpensive; therefore, it is often misrepresented as other street drugs, such as lysergic acid diethylamide (LSD), amphetamine, mescaline, or Δ-9-tetrahydrocannabinol (THC). Ketamine ("K," "Special K," "Super K," "cat valium") is commonly used as a "club drug" and is sometimes misrepresented as 3,4-methylenedioxymethamphetamine (MDMA; ecstasy). Ketamine is often diverted from veterinarian supplies. PCP ("angel dust," "dust") in powdered form is often applied to parsley, marijuana ("dusted joint," "superweed"), or tobacco cigarettes and smoked. Oral, intranasal and parenteral routes of administration are used by some. The combination of cocaine and PCP in a freebase smoking mixture is called "SpaceBase." Although ketamine is manufactured as an injectable liquid, it is frequently evaporated to a powder. The powder can be snorted or compressed into tablets.

Dextromethorphan is an antitussive agent found in some over-the-counter cough remedies. Its appeal as a drug of abuse may be because it is inexpensive, licit, lacks social disapproval associated with other drugs, and available over-the-counter, and abusers believe it to be safe because it is produced by a pharmaceutical company. Street names include "Skittles," "DXM," "Dex," "Robo," "C-C-C," and "Red Devils." Use is referred to as "dexing," "robotripping," and "robodosing." Dextromethorphan is the D-isomer of the codeine analog of levorphanol. The metabolic byproduct of dextromethorphan, dextrorphan, has weak N-methyl-D-aspartate (NMDA) antagonist properties.[61] When dextromethorphan is ingested in large doses, it produces effects similar to PCP or ketamine. When abused, doses range from 300 to 1,800 mg. The most commonly abused form is Coricidin HBP Cough and Cold (called "C-C-C" on the street) because it contains the highest concentration of dextromethorphan per dosage unit on the market (30 mg). Dextromethorphan is also available for sale on the internet in powdered form, which can be ingested orally or snorted. The dextromethorphan "high" can last 3 to 6 hours and can consist of euphoria, dissociation, hallucinosis, increased perceptual awareness, altered time perception, hyperexcitability, pressure of thought, and disorientation; increased blood pressure, heart rate, and body temperature; and blurry vision.[61] Other ingredients found in the over-the-counter preparations, such as acetaminophen, chlorpheniramine, guaifenesin, and alcohol, may be problematic when ingested in large doses. PCP is considered the typical dissociative drug, and review of its effects largely applies to ketamine and dextromethorphan as well.

Phencyclidine

PHENCYCLIDINE INTOXICATION

Persons who use PCP may appear agitated, diaphoretic, and disoriented. There is an increase in blood pressure, pulse, and temperature, and the person may experience vertical and horizontal nystagmus. These symptoms are consistent with PCP intoxication. PCP and ketamine are noncompetitive antagonists of the NMDA receptor subtype of the major excitatory neurotransmitter, glutamate. The dose, route of administration, and serum concentration of phencyclidine all influence the pharmacologic effects of this drug and, thus, the symptoms of intoxication.[61] PCP in low doses causes inebriation, ataxia, changes in body image, numbness, and a mind–body dissociative feeling. Horizontal or vertical nystagmus or both are often present, and the anesthetic effect of the drug raises the pain threshold. Amnesia can occur after intoxication.

As the dose of PCP increases, the patient may manifest agitation, combativeness, catatonia (ketamine users refer to this as a “k-hole”), and psychosis. The action of PCP on the autonomic nervous system becomes more prominent and is characterized by a confusing combination of adrenergic, cholinergic, and dopaminergic effects. A hypertensive response is typically encountered. Tachycardia, tachypnea, and hyperthermia may also be noted in the moderately intoxicated patient. The agitated, combative patient often has feelings of great strength. This, combined with the anesthetic effect of PCP, can result in serious injury because there is no pain sensation to stop the physical activity.

With large doses of PCP, marked CNS depression occurs, and nystagmus may no longer be present. In addition to the physiologic effects noted earlier, respiratory depression, seizures, acidosis, and rhabdomyolysis may further compromise the patient’s condition. Rhabdomyolysis, particularly in the presence of acidemia, can result in acute renal failure.[57] Opisthotonic posturing and muscular rigidity occur frequently in the severely intoxicated patient.

MEDICAL MANAGEMENT OF INTOXICATION

Diagnosis of PCP intoxication should be confirmed through a blood or urine specimen. Currently, no clinically useful antidote to PCP exists, and treatment should be supportive. Environmental stimuli should be minimized. Even attempts to talk down the patient may trigger a combative response, and chemical restraints may be indicated. Physical restraints may increase risk of rhabdomyolysis and should be reserved for patients who pose threat of great danger to themselves or others. Benzodiazepines are useful in the management of the anxious, agitated patient with mild to moderate PCP intoxication. If benzodiazepines are insufficient, haloperidol (5 mg IM) is effective.[57] Low-potency neuroleptics should be avoided because a greater possibility of precipitating a hypotensive response or a seizure exists.

Hypertension may be managed with β-blockers or calcium-channel blockers. Diazepam (5 to 10 mg intravenously to 30 mg total) is a useful anticonvulsant for the management of PCP-induced seizures.[57] Because extreme agitation, seizures, and hyperthermia can initiate rhabdomyolysis and secondarily cause myocardial, renal, or hepatic dysfunction, anxiolytics, neuroleptics, anticonvulsants, and cooling measures should be used as needed.

The urinary excretion of PCP (a basic compound) is enhanced when the urine is acidic; however, this approach is not recommended because it may exacerbate myoglobinuric renal failure.[51] Activated charcoal in a dose of 50 to 150 g initially, then 30 to 40 g every 6 to 8 hours, can prevent the intestinal reabsorption of this drug and promote its elimination.[57]

PSYCHOLOGICAL AND PROLONGED EFFECTS

Chronic PCP use can result in prolonged residual psychological symptoms, including anxiety, depression, and psychosis.[57]

Pharmacotherapy for these symptoms may be necessary. Prolonged psychiatric sequelae are almost always associated with premorbid psychopathology. Perceptual disorders, including auditory and visual hallucinations, such as after images seen following moving objects (“trails”), may also occur. Flashbacks (discussed in detail in the subsequent section on LSD) have been reported after PCP use.

The DSM-5 does not recognize PCP withdrawal; however, about one-fourth of heavy PCP users report symptoms after discontinuation of use.[57] These symptoms include depression, anxiety, irritability, hypersomnolence, diaphoresis, and tremor. Animal studies have described a withdrawal syndrome, but it is unclear whether a true withdrawal syndrome occurs in humans.[57] Currently, no pharmacologic treatments for PCP use disorder exist. Some animal data indicate neurotoxicity; however, the long-term consequences and significance for humans are unknown and require further study. Chronic users often complain of feeling “spaced”; they may be irritable and antisocial and feel depersonalized and isolated from people. Memory lapses, speech and visual disturbances, and confusion have been described in long-term users as well.

HALLUCINOGENS

Hallucinogens can be categorized as indole alkylamines (e.g., LSD, psilocybin, and dimethyltryptamine) or phenethylamines (e.g., mescaline; MDMA). LSD is considered the prototype hallucinogen. Although MDMA is classified as a phenethylamine, it has structural similarities to amphetamine and mescaline. It has been labeled an entactogen or empathogen because of its strong empathy-producing effects and mild hallucinogenic effects. The term entactogen can be translated as “a touching within.” Hallucinogens are commonly referred to as psychedelics.

In 2014, 1.2 million Americans were current hallucinogen users. The popularity of MDMA (ecstasy, X) has risen dramatically in recent years, partly because of its use as a “club drug.” In 2014, 609,000 Americans reported using MDMA sometime in the past month.[4] The usual pattern of use for hallucinogens is occasional self-administration for enhancement of recreational activities, such as dancing, or for "mind expansion." Certain individuals may develop psychological dependence and use hallucinogens in a more chronic and compulsive manner.

LSD

EFFECTS

Perhaps the most famous of all hallucinogens, LSD-25 was first synthesized by Albert Hofmann of Sandoz Laboratories in 1938. It was developed as an analeptic agent but produced significant uterine stimulation and caused experimental animals to become excited or cataleptic. Five years later, while resynthesizing LSD-25 for further pharmacologic testing, Dr. Hofmann experienced a restlessness that forced him to go home. This was followed by 2 hours of intense visual hallucinations of kaleidoscopic images and colors. Later, he identified LSD-25 as a potent hallucinogen. Clinical experimentation produced hundreds of papers describing LSD as a drug that could facilitate psychotherapy, particularly in the management of addictive behavior. Widespread public self-experimentation with LSD for recreation and self-exploration, coupled with growing attention to adverse psychological consequences, led Sandoz to discontinue production of LSD-25 (as well as psilocybin, psilocin, and related congeners) in August 1965. The United States made LSD a schedule I controlled substance in 1970 after the proliferation of illicit suppliers to meet the huge public demand for this drug.

Although the mechanism of action of classic hallucinogens is not fully understood, they appear to predominately act as agonists or partial agonists at serotonin (5-HT) receptors, specifically the 5-HT_2 receptor.[63] LSD, one of the most potent hallucinogens known, is active at doses of 25 to 250 mcg. Most users take about 100 to 150 mcg of LSD for a significant effect. This dose produces mild to moderate sympathomimetic effects, profound visual hallucinosis, and the sensation of disordered integration of sensory input. For example, sounds and music are perceived as visual imagery, odors are felt, and inanimate objects assume lifelike qualities. In addition to these sensory-perceptual effects, psychic effects occur, such as depersonalization, dreamlike feelings, and rapid alterations of affect. These are accompanied by somatic effects, including dizziness, nausea, weakness, tremor, and tingling skin.[63] These combined effects begin within an hour of ingestion of LSD and usually peak in intensity during the first 2 to 4 hours. After taking LSD, most people feel they have returned to a normal psychological state by 10 to 12 hours.[64] Within an hour after ingestion, a person will begin to experience altered sensations of his/her surroundings, in addition to some psychic and somatic effects.

ADVERSE EFFECTS

The most frequently encountered adverse reaction associated with the hallucinogenic drugs is a mental state of acute anxiety and fear, typically referred to as a "bad trip." The hallucinogen experience is influenced by set (the user's mental state and expectations of drug effects) and setting (the environment in which drug use takes place, including the social conditions). Users may be able to calm themselves without outside intervention. The initial therapy of people undergoing a bad trip is frequently called "reality therapy" and consists of talking down the fear and panic. This consists of getting the person to a quiet, relaxed setting and helping him or her focus on explanations for the uncertainties that are causing the panic. This process also tends to reassure the person that he or she is in a safe physical environment and that the drug effects will diminish in a few hours. Most of these bad trips are resolved during the state of intoxication (generally, 6–12 hours), but some last as long as 24 to 48 hours.[57]

If the talk-down approach is not successful in resolving the panic, drug therapy can be considered. Sedation with an oral benzodiazepine (i.e., diazepam 10–30 mg) or a parenteral benzodiazepine (i.e., lorazepam 2 mg IM) will frequently alleviate the panic.[57] Supportive talking down should be continued because the benzodiazepine will not stop the trip; it will simply sedate the patient. Haloperidol 2 mg IM may also be used if benzodiazepines are insufficient. Phenothiazines should not be used for initial management of bad trips because they have been associated with poor outcomes.[57]

Regarding adverse physical effects, classic hallucinogens have a high margin of safety, although patients should be monitored for seizures or elevations in body temperature, which may indicate a potential hyperthermic crisis. Anticonvulsant therapy may not be effective until body temperature has been lowered.[57]

FLASHBACKS AND LONG-TERM EFFECTS

Use of hallucinogens can trigger a transient psychosis or unmask an underlying psychiatric disorder; however, a true psychotic episode is rare. Psychiatric conditions after hallucinogen use that persist more than a month are likely caused by preexisting psychopathology.[57] Hallucinogen use does not seem to be associated with any cognitive impairment.[64]

Hallucinogen persisting perceptual disorder (HPPD), commonly referred to as flashbacks, is characterized by recurrences of part

or all of the hallucinogenic drug experiences after a period of normal consciousness in a person who used the drug previously. The flashbacks may last from minutes to days or months (usually a few hours). The estimated prevalence of flashbacks varies widely in studies, and the etiology is still unclear.[65] Flashbacks can occur spontaneously or be triggered by exercise, stress, or another drug (e.g., marijuana).[64] Treatment remains anecdotal; no randomized, controlled trials have evaluated the efficacy of pharmacotherapy for HPPD.

LSD and other classic hallucinogens have low potential for chronic use disorder. There does not appear to be a clinically important withdrawal syndrome associated with their use. The rapid development of tolerance that occurs with these drugs may explain the intermittent use patterns commonly seen.

MDMA

CASE 90-8

QUESTION 1: R.X. and her friend P.B. go to "raves" (all-night dance parties) every weekend and usually take ecstasy (MDMA). R.X. says it makes her feel like "I love everyone around me," and P.B. likes to be able to "dance all night without getting tired." Are these effects common with MDMA?

Merck Pharmaceuticals patented MDMA in 1914, but it was not until the 1950s that its use was examined in animal studies, when the US Army Intelligence investigated it as a "brainwashing" agent. By the late 1970s, a few therapists and psychiatrists began using the drug with reported success in patients with a wide range of conditions.[66] MDMA produces a very manageable and comfortable entactogenic effect, during which the person has a clear sensorium. The experience can be recalled in detail, and the insights gained during the session can be incorporated into normal life. The public gave several names to this drug, such as ecstasy, XTC, Adam, and M&Ms. The media became aware of the anecdotal reports from both psychiatrists and people self-experimenting with MDMA. In 1985, the DEA made MDMA a schedule I drug. Subsequently, supplies of the drug proliferated in the public illicit marketplace, and its popularity soared. In 2001, after successful lobbying by researchers interested in reinstituting MDMA in clinical practice, the FDA granted approval for a pilot study investigating the therapeutic use of MDMA in the treatment of posttraumatic stress disorder (PTSD). Results of this placebo-controlled study indicate that MDMA is very effective (83% vs. 25%) in treating PTSD.[67] The effects of MDMA are mainly exerted by three neurochemical mechanisms: blockade of serotonin reuptake, stimulation of serotonin release, and stimulation of dopamine release.[68] The common psychological effects of MDMA intoxication include an overall heightened sense of empathy, interpersonal closeness, increased acceptance of others, and a powerful sense of well-being.[69] The experience is influenced by set and setting. The amphetamine-like side effects include mydriasis, tachycardia, sweating, increased energy and alertness, bruxism, nausea, and anorexia.[70] Users generally ingest MDMA in tablet form, and the onset of action is usually after 30 to 60 minutes. Some users take a "booster" dose after 2 hours. The usual duration of action of MDMA is 4 to 6 hours, and the half-life is approximately 8 hours. MDMA users in the rave scene often "stack" multiple doses, and polydrug use is common. The combined use of ecstasy and LSD is referred to as "candy flipping."[68]

R.X.'s feelings of love for everyone are consistent with the empathogenic effects of MDMA, whereas P.B. is enjoying the amphetamine-like effects of increased energy to dance all night.

ADVERSE EFFECTS

CASE 90-8, QUESTION 2: Several hours after taking MDMA, P.B. is still dancing. She begins to feel hot and realizes she is profusely sweating. On her way to the bar for a drink, she begins to feel confused and collapses to the floor. Her friends witness her having a seizure and call 9-1-1. What is happening to P.B.?

The rave scene, with its crowded conditions and often-high ambient temperatures, has contributed to many adverse effects associated with MDMA ingestion. Because of their increased physical activity, the ravers may become dehydrated. Additionally, supplies of MDMA have been notoriously unreliable. Many other drugs have been misrepresented as MDMA, including other phenethylamines such as 3,4-methylenedioxy-amphetamine (MDA) and paramethoxyamphetamine (PMA); amphetamine; cocaine; opiates; ketamine; and dextromethorphan. The common polydrug use practiced at raves compounds the problem. Dextromethorphan taken at high doses for its dissociative properties competes with MDMA for hepatic metabolism, and its anticholinergic effects block perspiration, potentially leading to overheating.[66]

The most dangerous adverse physical effect of MDMA is hyperthermia. MDMA has a slight affinity for the 5-HT_2 receptor, and the increased body temperature may be the result of this activation.[68] The hyperthermia has led to rhabdomyolysis, and acute renal and hepatic failure, disseminated intravascular coagulation (DIC), and death.[71] DIC has been the most common cause of death. Treatment of hyperthermia involves cooling measures and IV fluids. Benzodiazepines (e.g., lorazepam 2 mg IM or IV) and dantrolene (1 mg/kg IV) may be helpful. Other adverse physical effects can include hypertension, cardiac arrhythmias, convulsions, cerebrovascular accident, hepatitis, and hyponatremia (from over ingestion of water as a harm reduction measure to avoid hyperthermia).[70,71] In 2011, there were 22,498, emergency department visits associated with MDMA use.[72] Adverse psychological effects are also possible, including anxiety, depression, panic attacks, agitation, paranoia, and rarely psychosis. The treatment of these psychological adverse effects is the same as for those associated with the classic hallucinogens, including talk-down therapy and benzodiazepine administration. P.B. may be suffering from MDMA-induced hyperthermia and needs urgent medical evaluation.

LONG-TERM EFFECTS

CASE 90-8, QUESTION 3: R.X. has read in the newspaper that MDMA is associated with “brain damage” and is worried that she has caused permanent damage to her brain. What are the long-term effects of MDMA?

Animal studies have consistently demonstrated long-term MDMA-induced serotonin depletion. This has been evidenced by lower levels of serotonin, decreased metabolite levels, lowered levels of tryptophan hydroxylase, and loss of serotonin reuptake transporters.[66] This may explain the induction of panic attacks for chronic users. MDMA damages serotonin axonal projections; axonal resprouting and regeneration do occur, but it is unclear whether these new projections are damaged.[66,73] Both hepatotoxicity and neuronal toxicity occur with MDMA use and is suspected to be due to oxidative stress, mitochondrial dysfunction, and excitotoxicity.[60]

Several retrospective studies in humans have claimed lowered cognitive performance in MDMA users compared with nonusers. These studies have confounding variables, such as other drug use and adulterant exposure and lifestyle factors.[66,73]

Use of MDMA does not appear to produce physical dependence, but some users may become psychologically dependent. Tolerance to the empathogenic effects develops rapidly and may last 24 to 36 hours. This may explain in part the more common practice of sporadic dosing of the drug.[57,69] No distinctive withdrawal syndrome has been described that would require pharmacologic treatment.

MARIJUANA

Marijuana is the most widely used illicit substance in the United States. In 2014, 35.1 million Americans reported using marijuana in the past year.[4] The main psychoactive ingredient in the Cannabis sativa plant is Δ-9-tetrahydrocannabinol (THC), although the plant is known to contain more than 70 cannabinoids.[74] In the United States, the dried, chopped leaves and flowers of the Cannabis plant (grass, pot, weed, green bud, chronic, mary jane) are rolled into a cigarette paper (marijuana cigarette, known as a joint or blunt; a “roach” is the butt of the marijuana cigarette) or smoked in a pipe or water pipe (“bong”). Each joint usually weighs 0.5 to 1 g, for a THC content of about 5 mg (very weak), 30 mg (average), or 150 mg (highest-quality sinsemilla). The sinsemilla (Spanish for “without seeds”) growing technique involves separating the female plants from the males before pollination occurs. This results in female plants with higher amounts of THC, up to 14%.[75]

The raw resin of the Cannabis plant can be pressed into cakes, balls, or sticks, called hashish (“hash,” “temple balls”), which is smoked or eaten. Hashish can contain up to 8% THC. The oils can be extracted from the plant with organic solvents to produce “hash oil,” perhaps the most potent Cannabis derivative, with THC concentrations of up to 50%.[75]

Researchers in cannabinoid neurobiology have discovered two cannabinoid receptors in the CNS: CB_1 and CB_2; however, additional receptors have been proposed. Research has demonstrated that the main pharmacologic and addictive effects are almost completely mediated by the CB_1 receptor.[75] In addition, five endogenous cannabinoids (endocannabinoids) that act at the cannabinoid receptors have been discovered.[76] The best known are arachidonic acid ethanolamide (anandamide) and 2-arachidonoylglycerol (2-AG).[76] Considerable evidence exists supporting the role of THC–opioid interactions with enhanced antinociception. Cannabinoids have been shown to release endogenous opioids, and cannabinoid receptors colocalize with substance P (the neurotransmitter responsible for transmitting pain information) receptors in the striatum. Subsequently, investigation of THC as an adjunct to opioid treatment of pain, prevention of opioid tolerance, and dependence is underway.[75]

Marijuana's therapeutic potential has been the center of much public controversy. Research on the effects of cannabinoids has led to several potential therapeutic uses, including relief of nausea and vomiting, appetite stimulation, and treatment of pain, epilepsy, glaucoma, and movement disorders (Parkinson disease, Huntington disease, Tourette syndrome, multiple sclerosis).[75,77] In 1999, the State of California passed the law SB847, which commissioned the University of California to establish the Center for Medicinal Cannabis Research (CMCR) to expand scientific knowledge on purported therapeutic usages of marijuana. The center's 2010 report to the California legislature and governor presented clinical trial findings demonstrating that cannabis has analgesic effects in pain conditions secondary to injury or disease and that cannabis reduces MS spasticity.[78] A synthetic form of THC, dronabinol, is available as prescription tablets, and a synthetic cannabinoid, nabilone (Cesamet), is available as capsules, but advocates of medicinal marijuana use argue that inhalation allows for faster onset and easier titration of the dose. In addition, nauseated patients want to avoid the oral route of administration. Future research focuses on developing a safer delivery system that will be reliable, rapid, and safe. An oromucosal spray, Sativex, derived from botanical material, is under investigation in the United States. The principal active components are THC and cannabidiol. This cannabis extract spray has been approved in Canada, and is also being used in the United Kingdom. A capsule formulation containing a mixed ratio of THC and cannabidiol produced by Cannador in Germany is also available.[75] Other alternative delivery methods may include vaporization, patches, and suppositories.

Effects

CASE 90-9

QUESTION 1: P.H. is a 16-year-old male who is offered a marijuana cigarette (joint) by one of his friends. He smokes it and begins to feel light-headed and euphoric. He begins laughing at everything around him. Thirty minutes later he and his friend become very hungry (“the munchies”) and eat several candy bars. Which of P.H.’s symptoms are consistent with marijuana use?

The pharmacologic effects sought by most users of cannabis products are sedation, mental relaxation, euphoria, and mild hallucinogenic effects, and these effects depend on set and setting. Other common effects that are usually perceived as pleasurable include silliness, subjective slowing of time, gregariousness, hunger, and mild perceptual changes of all the senses that engender an absorbing fascination with music, eating, and other sensual and sensory activities. The state of mind generated is referred to as “stoned,” “high,” “loaded,” “wasted,” and many other colloquial terms. Smoking marijuana typically causes numbness and tingling of the extremities, light-headedness, loss of concentration, and a floating sensation in the first 3 or 4 minutes. Some of these effects are probably caused by the hyperventilation associated with deep inhalation of the smoke (referred to as a “hit” or “toke”) and breath holding to allow maximal absorption from the lungs. During the first 10 to 30 minutes, the user may experience tachycardia (possibly palpitations), mild diaphoresis, conjunctival injection (“red eye”), drying of the mouth, weakness, postural hypotension, periods of tremulousness, incoordination, and ataxia along with euphoria and the mental effects described above. These effects usually resolve by 1 to 3 hours and are followed by a 30- to 60-minute period of sleepiness before complete clearing and return to normal consciousness. Oral ingestion of cannabis products may delay the onset of effects by 45 to 60 minutes and prolong the duration.[75] P.H. is experiencing euphoria, giddiness, and increased appetite, consistent with marijuana intoxication.

Adverse Effects

CASE 90-9, QUESTION 2: P.H. smokes more marijuana with his friend. He liked it so much the first time, he decides to take several “hits” this time. He begins to think his friend is laughing at him and notices his heart is beating rapidly. He starts to panic. Is P.H.’s reaction caused by the marijuana?

Consistent with its widespread use, marijuana was the second most frequently mentioned illicit substance in emergency department episodes in the United States in 2007. A total of 308,547 marijuana-related emergency department (ED) visits were reported in 2007.[58] These visits include marijuana in combination with other drugs. As the percentage of THC has increased in marijuana, so have the ED visits. The majority of ED visits are from unexpected reactions, such as anxiety, paranoia, and panic attacks. Despite these numbers, there are no documented cases of fatality in humans from marijuana overdose, and adverse effects tend to be self-limiting and often do not require medical treatment.

A syndrome consisting of anxiety, paranoia, depersonalization, disorientation, and confusion that can lead to panic states and incapacitating fear is perhaps the most frequently reported adverse effect of marijuana. Comforting reassurance (talk-down) and reducing stressful stimuli can alleviate this condition. The dysphoria and anxiety usually resolve in a few hours or less with such an approach. More severe incidents that evolve into panic reactions that are not resolved by sympathetic counseling may be relieved with oral benzodiazepine therapy in a dose equivalent to 5 to 10 mg of diazepam.[57] These adverse psychological reactions to cannabis products commonly occur with inexperienced users, high doses, concomitant use of other psychoactive drugs, and overtly stressful situations. Severe reactions requiring pharmacologic therapy are rare. A review of the literature found that cannabis use increases the risk of developing psychotic disorders among vulnerable or predisposed individuals and negatively affects the course of preexisting chronic psychosis.[79]

Other adverse effects can include slowed psychomotor responses and short-term memory loss. Slowed psychomotor responses have been shown in certain groups of acutely intoxicated subjects and chronic users. Even medical marijuana users have shown a steep increase in automobile accidents. Short-term memory loss is a frequently documented acute, reversible effect of marijuana intoxication as well.

The paranoid ideation and panic reaction of P.H. could certainly be caused by the high dose and his inexperience with marijuana.

Long-Term Effects

CASE 90-9, QUESTION 3: P.H. continues to smoke marijuana daily. What are possible long-term effects of marijuana use?

Chronic use of cannabis has been alleged to produce an “amotivational syndrome” characterized by apathy, lack of long-term goal achievement, inability to manage stress, and generalized laziness.[75,80,81] Cognitive impairment can occur after heavy marijuana use, but appears to be reversible with abstinence.[82] However, the adolescent brain has shown a drop in IQ related to marijuana use that does not reverse even after 1 year of abstinence.[83] The impairment is more pronounced the longer the drug is used.[67] Other concurrent drug use may also contribute to cognitive impairment associated with marijuana use. As noted above, there is a dose-dependent risk of chronic use resulting in an increased risk of developing a psychotic illness later in life. [79,84] Chronic users will have worse periodontal health.[85] The pulmonary complications of chronic heavy marijuana use are potentially significant. Chronic cough, sputum, wheezing, bronchitis, and cellular changes typical of chronic tobacco smokers are reported in chronic cannabis smokers.[75,86] THC has been shown to be a potent bronchodilator. Both oral and smoked THCs were shown to produce significant bronchodilation when given to healthy subjects. The bronchodilatory response in asthmatics given THC has been shown to be less vigorous.[87] Tolerance to these effects can develop after some weeks, and chronic marijuana smoking results in increased airway resistance and decreased pulmonary function.[75] Many of the same carcinogens in nicotine cigarettes are also found in marijuana smoke and risk of some cancers is increased compared to nonusers.[75,81] Aspergillus-contaminated marijuana has been reported to cause pulmonary fungal infections in immunocompromised patients, who may be using the drug for its medicinal value.[88]

Tolerance to the psychoactive effects of marijuana does develop. Chronic users may not experience the full range of effects as new users unless they abstain for several days or weeks to regain initial sensitivity to the cannabis, and chronic users can tolerate large doses that generally are toxic to novices. Tolerance develops rapidly to both physiologic and psychological effects of cannabis. Dependence characterized by a physical withdrawal syndrome occurs after chronic high-dose use of cannabis. The withdrawal syndrome can involve anxiety, depression, irritability, restlessness, anorexia, insomnia and vivid or disturbing dreams, sweating, tremor, nausea, vomiting, and diarrhea.[57,75,83] Dysphoria and malaise similar to that experienced with influenza can also occur. The cumulative dose of cannabis and duration of use necessary to produce dependence is unknown. The withdrawal syndrome is generally mild and self-limiting, and pharmacologic treatments usually are not required.

Marijuana has been labeled as a “gateway drug,” meaning that it will lead to the use of “harder” drugs, such as cocaine or heroin. Marijuana is the most widely used illicit drug, but use of drugs such as alcohol and tobacco often predates marijuana use. No studies have conclusively demonstrated a causal link between marijuana use and subsequent other drug use.[75]

There are clear acute and chronic risks involved with marijuana use. As more states legalize it for recreational and “medical” purposes, researchers will be able to define and predict the fullness of these problems.

INHALANTS

The introduction of anesthetics (nitrous oxide, chloroform, and ether) to medicine in the early 1800s also promoted the widespread and popular recreational use of these inhalants for mind-altering recreational purposes. Today, abused inhalants include a wide variety of chemicals that are found readily in homes or workplaces, or purchased at retail establishments. Inhalants are commonly subdivided into three main categories: the volatile solvents (mostly hydrocarbons); volatile nitrites (amyl, butyl, isobutyl, cyclohexyl); and nitrous oxide (laughing gas). The fumes or vapors of these liquids, or paste in the case of glue, are directly inhaled out of their containers (“sniffing”); poured onto a rag that is held to the nose (“huffing”); poured into a plastic bag (“bagging”); or merely cupped in the hands and inhaled. Aerosols and gaseous substances such as nitrous oxide are also used to inflate a balloon and then inhaled out of the balloon by the user. These products can also be ingested orally or sprayed directly into the mouth. Volatile solvents include gasoline, toluene, kerosene, alcohols, airplane glue, lacquer thinner, acetone (nail polish remover), benzene (nail polish remover, model cement), naphtha (lighter fluid), plastic cement, liquid paper (i.e., White Out, usually containing 1,1,1-trichloroethane, also trichloroethylene and perchloroethylene), and many others. The volatile nitrites, once widely available, are prohibited by the Consumer Product Safety Commission but can still be found, sold in small bottles, labeled as “video head cleaner” or “room odorizer.” Amyl nitrite is used medically as a vasodilator for treatment of angina and requires a prescription. The volatile nitrites are commonly referred to as “poppers,” because of the sound made when an ampule of amyl nitrite is broken open. The most commonly used inhalants are glue, shoe polish, toluene, and gasoline.[89] The use of multiple products is common. Silver and gold paints are popular because they contain more toluene than paints of other colors.[90]

Inhalant use is most common among younger individuals (consistently highest annual prevalence among 8th graders) and tends to decline as youth grow older. The decline likely reflects that other drugs become available and are substituted. Abuse of inhalants is believed to be popular among children and adolescents because of their low cost, easy availability, rapid onset, and low threat of legal intervention. Additionally, they are easily concealed.

The 2009 Monitoring the Future (MTF) study found that 12.5% of 8th, 10th, and 12th graders have abused inhalants.[91] The MTF and other national surveys of adolescents have found that after marijuana, inhalants are the second most widely used class of illicit drugs for 8th graders. Most inhalant users, however, have used alcohol or cigarettes previously.[92] These surveys, most of which are administered in schools, likely underestimate the true prevalence, as a small but high-risk group (incarcerated, homeless, and transient adolescents) are not included in the surveys.

Effects of Inhalants

Inhalant abuse includes a broad range of chemicals, and they likely have different pharmacologic effects. In fact, the mechanisms of action of the volatile inhalants are poorly understood. Nearly all have CNS depressant effects. Evidence from animal studies suggests the effects and mechanism of action of volatile solvents are similar to those of alcohol and sedative-hypnotics.[93]

Gases and vapors are rapidly absorbed when inhaled and, because of their high lipophilicity, tend to distribute preferentially to lipid-rich organs such as the brain and liver.[93] Expired air is the major route of elimination, and most are metabolized to some extent. Inhalation of these products produces a temporary stimulation and reduced inhibitions before the depressive CNS effects occur. Acute intoxication is associated with euphoria, giddiness, dizziness, slurred speech, unsteady gait, and drowsiness.[90] As the CNS becomes more deeply affected, illusions, hallucinations, and delusions develop. The user experiences a euphoric, dreamy high that culminates in a short period of sleep. The intoxicated state lasts a few minutes, but users may continue to inhale repeatedly for several hours. Nitrous oxide is an antagonist of the NMDA subtype of the glutamate receptor.[61] Its pharmacologic effects are poorly understood. It produces euphoria and symptoms of intoxication similar to those described for the volatile solvents.

The major effect of the volatile nitrites is the relaxation of all smooth muscles in the body, including the blood vessels. This usually allows a greater volume of blood to flow to the brain. The onset of effects takes 7 or 8 seconds and the effects last about 30 seconds. A certain “rush” occurs, which may be followed by a severe headache, dizziness, and giddiness. The volatile nitrites are frequently used in the context of sexual activity, because of the effect of increased tumescence and relaxation of smooth muscle.[93]

Acute and Chronic Toxicities Associated with Inhalants

The wide variety of chemicals inhaled causes a tremendous range of toxicities. Toxicity depends on the chemical, and on the magnitude and duration of exposure. Complications can result from the effects of the solvents or other toxic ingredients, such as lead in gasoline. The lipophilicity of the volatiles enhances their toxicity. Injuries to the brain, liver, kidney, bone marrow, and particularly the lungs can occur, and they may result from the effect of heavy exposure or hypersensitivity. Inhalant abusers may develop irritation of the eyes, nose, and mouth, including rhinitis, conjunctivitis, and rash.[93] Methemoglobinemia has been associated with volatile nitrite use.

Deaths from inhalant use are well documented and may occur from overdose or trauma (falls, drowning, hanging). Death from overdose is often caused by respiratory problems or suffocation after CNS depression.[93] Deaths caused by asphyxiation, convulsions, coma, and aspiration of gastric contents have occurred.[90] Acute cardiotoxicity resulting in cardiac arrest may cause sudden death. Referred to as “sudden sniffing death,” it is likely caused by sensitization of the myocardium to catecholamines, exacerbated by physical exercise, resulting in fatal ventricular arrhythmias.

Many of the inhalants produce neurotoxicity, which can range from mild impairment to severe dementia. Neurologic deficits include cognitive impairment, ataxia, optic neuropathy, deafness, and disorders of equilibrium. Loss of white matter, brain atrophy, and damage to specific neural pathways can result from chronic exposure to some inhalants. Some damage to the nervous system and other organs may be at least partially reversible when inhalant use is discontinued.[90]

Inhalant Abuse and Dependence

Compulsive use has been documented with inhalants, although inhalant abuse and dependence is a neglected area of research. Animal studies have shown some of the abused inhalants to have reinforcing properties.[93,94] It is unclear whether a true withdrawal syndrome occurs with chronic use of inhalants. Inhalant use is typically episodic in nature, and thus users may not be exposed to levels with sufficient frequency necessary to develop physical dependence or tolerance.

ALCOHOL USE DISORDERS

Alcohol Content and Definitions

Beverages containing alcohol (ethanol) have a wide range of ethanol content. Alcoholic proof is a measure of how much ethanol is in an alcoholic beverage, and is twice the percentage of alcohol by volume (ABV), the unit that is commonly used as percent. This system dates to the 18th century, and perhaps earlier, when spirits were graded along with gunpowder. A solution of water and alcohol “proved” itself when it could be poured on a pinch of gunpowder and the wet powder could still be ignited. If the gunpowder did not ignite, the solution had too much water in it and the proof was considered insufficient. A “proven” solution was defined as 100 degrees proof (100).[95,96] In the United States, the proof is twice the percentage of alcohol content measured by volume at a temperature of 60°F. Therefore “80 proof” is 40% ABV, and pure alcohol (100%) is “200 proof.” One hundred percent ethanol does not stay 100% because it is hygroscopic and absorbs water from the atmosphere.

Legally, in the United States, beers containing up to 0.5% ABV can be called nonalcoholic. Light beers range from 2% to about 4% ABV; beers range from 4% to 6% ABV; ales, stouts, and specialty brews can be as high as 10% ABV. Wines are produced at about 14% to 16% (28–32 proof), because that is the point in the fermentation process at which the alcohol concentration denatures the yeast. Stronger liquors are distilled after fermentation is complete to separate the alcoholic liquid from the remains of the source of sugar (e.g., grain, fruit). Distilled liquor cannot be stronger than 95% (190 proof). A standard drink in the United States is considered to be 0.5 ounces or contain 15 g (0.5 fl oz of absolute alcohol) of alcohol. This is equal to 12 ounces (355 mL) of 5% beer, 5 ounces (148 mL) of 12% wine, or 1.5 ounces (44 mL) of 40% spirits.[95,96]

Epidemiology

Slightly more than half (52.7%) of Americans age 12 or older reported being current drinkers (at least one drink in the past 30 days) of alcohol in the 2014 National Survey on Drug Use and Health survey.[4] This translates to an estimated 137 million people, which is similar to the 2005 estimate of 126 million people (51.8%). In 2014, heavy drinking (five or more drinks on the same occasion on each of 5 or more days in the past 30 days) was reported by 6.2% of the population age 12 or older.[4]

Approximately 10% of Americans will be affected by alcohol use disorder sometime during their lives.[97,98] Treatment of alcohol dependence consists mainly of psychological, social, and pharmacotherapy interventions aimed at reducing alcohol-related problems.[99] Treatment usually consists of two phases: detoxification and maintenance.

The rationale for pharmacotherapy is based on several considerations. Advances in neurobiology have identified neurotransmitter systems that initiate and sustain alcohol drinking; pharmacologic modification of these neurotransmitters or their receptors may alter dependence.[100] Promising genetic research confirms that alcoholics are a heterogeneous population and that several gene variations can predispose some to increased alcohol use whereas other gene variations can confer protection.[100] Animal models have identified pharmacologic agents that reduce alcohol consumption in animals, suggesting similar agents could reduce alcohol consumption in humans.

Risks and Benefits of Alcohol Consumption

The role of alcohol in the development of medical problems such as cardiovascular disease, hepatic cirrhosis, and fetal abnormalities is well documented. Alcohol use and abuse contribute to thousands of injuries, auto collisions, and violence.[101] Alcohol can dramatically affect worker productivity and absenteeism, family interactions, and school performance.[102] Some studies suggest, however, that individuals who abstain from using alcohol may also be at greater risk for a variety of conditions, particularly coronary heart disease (CHD), than people who consume small to moderate amounts of alcohol.[103]

A number of studies have documented an association between moderate alcohol consumption and lower risk for CHD and myocardial infarction (MI).[104,105] Binge drinking after an MI, however, increases the risk of mortality.[106] US guidelines define moderate drinking as one drink or less daily for women or people age 65 and older, and two drinks or less per day for men.[107] An association between moderate drinking and lower risk of CHD does not mean that alcohol is the cause of the lower risk. A review of population studies indicates that the higher mortality risk among abstainers may be attributable to socioeconomic and employment status, mental health, and overall health, rather than abstinence from alcohol use.[108] Benefits of moderate drinking on CHD mortality are offset at higher drinking levels by increased risk of death because of other types of heart disease, cancer, cirrhosis, and trauma. The risk of a disease outcome from low to moderate drinking is less than the risk from either no drinking at all or heavier drinking. This produces a U-shaped curve when examining the association of alcohol consumption with rates of deaths from all causes.[103]

The exact mechanism by which alcohol use may be protective against morbidity in those with CHD is not clear. Some evidence indicates that different types of alcoholic beverages, such as red wines, which are high in tannins, may lower blood lipids and fats by increasing antioxidants.[106] Specifically, the mechanisms by which alcohol may reduce the risk of CHD include increasing levels of high-density lipoprotein cholesterol, decreasing levels of low-density lipoprotein cholesterol, prevention of clot formation, reduction in platelet aggregation, and lowering of plasma apolipoprotein(a) concentration, resulting in the attenuation of the formation of atheroma and decreasing the rate of blood coagulation.[109,110] It is also possible, however, that how a person drinks alcoholic beverages matters as well. For example, wines are ingested more slowly as they are typically consumed in moderate amounts with food. Binge drinking of any type of beverage, however, increases the risk of mortality from CHD in particular.[106]

Pharmacokinetics and Pharmacology

When consumed in amounts typical of normal social drinking, the absorption of ethanol from the stomach, small intestine, and colon is complete; however, the rate is variable. Peak blood ethanol concentrations after oral doses in fasting subjects generally are reached in 30 to 75 minutes, but several factors can influence the rate and extent of absorption.[111] The most rapidly absorbed formulations are carbonated beverages containing 10% to 30% ethanol. In contrast, high concentrations of alcohol can produce vasoconstriction in the gastrointestinal (GI) mucosa, which results in slowed or even incomplete absorption of ethanol. Absorption of ethanol from the small intestine appears to be more rapid than any other part of the GI tract and does not depend on the presence or absence of food. Factors that control the rate of gastric emptying significantly control the rate of absorption by controlling the rate at which ethanol is delivered to the small intestine.[112,113] For example, food in the stomach slows the absorption of ethanol, probably by slowing gastric emptying. The level of intoxication achieved is not solely related to the plasma concentration. For any particular plasma concentration, greater cognitive impairment is seen during times when the plasma level is rising compared with when ethanol is primarily being eliminated. The degree of intoxication also appears to be directly related to the rate at which pharmacologically active plasma concentrations are attained. Alcohol negatively affects cognitive performance and has a differential effect on the descending versus ascending limb of the blood alcohol concentration (BAC) curve. The latter finding may have important ramifications relating to the detrimental consequences of alcohol intoxication.[114]

The blood alcohol level (BAL) or BAC is calculated using the weight of ethanol in milligrams and the volume of blood in deciliters. This yields a BAC expressed as a proportion (i.e., 100 mg/dL or 1.0 g/L) or as a percentage (i.e., 0.10% alcohol). Ethanol concentrations are usually converted to equivalent BACs for standardization purposes when measured in other body fluids.

The alcohol dehydrogenase (ADH) pathway is the major enzyme system responsible for alcohol metabolism in humans. The main alcohol metabolism occurs with ADH isoenzymes, in the stomach (ADH6 and ADH7) and in the liver (ADH1, ADH2, and ADH3). The pathway involves conversion of ethanol to acetaldehyde by these ADH isoenzymes, resulting in the reduction of nicotinamide adenine dinucleotide (NAD) to NADH. In the second step, acetaldehyde is converted to acetate via the enzyme aldehyde dehydrogenase, which also reduces NAD to NADH. These are the rate-limiting steps in ethanol metabolism, and this route becomes saturated when large amounts of ethanol deplete NAD.[115] Acetate ultimately is converted to carbon dioxide and water. An additional pathway that is more involved in alcohol-dependent individuals than those who are not involves the catalase pathway of peroxisomes and the microsomal ethanol oxidizing system (MEOS), in the smooth endoplasmic reticulum. The main functional component of the MEOS is the cytochrome-P450 (CYP) 2E1.

Of a dose of ethanol, 90% to 98% is oxidized in the liver, with the remaining drug excreted unchanged in the alveolar air and urine. Ethanol metabolism formerly was described by zero-order kinetics; however, Michaelis–Menten and other nonlinear, concentration-dependent models are more accurate.[116,117] In some situations, a portion of the absorbed dose of ethanol does not appear to enter the systemic circulation, suggesting first-pass metabolism. The relative contribution of hepatic versus gastric ADH to this response continues to be debated, however.[118,119] Using a two-compartment, Michaelis–Menten pharmacokinetic model as well as experimental data, it appears that gastric metabolism contributes negligibly to first-pass metabolism.[120–122] They believe that gastric metabolism accounts for sex and ethnic differences

---

in first-pass metabolism. Estimates of total gastric ADH suggest that the enzyme can metabolize 0.9 to 1.8 g/hour of ethanol, depending on the concentration of ethanol consumed.[123] The extent of first-pass extraction tends to decrease as the dose of alcohol increases. This is likely because of saturation of ADH, regardless of the source. When plasma ethanol levels are greater than 0.2 g/mL, the ADH system becomes saturated. As hepatic ADH becomes saturated, there is increased unchanged excretion of alcohol. This results in a more intense odor of alcohol on the breath as the plasma ethanol concentration increases. The metabolism of alcohol also then tends to become nonlinear because of stimulation of CYP2E1, which produces metabolic tolerance to ethanol in chronic users.

Lower first-pass metabolism has been found in alcohol-dependent individuals, women, the elderly, and Japanese subjects.[120,122] Gastric ADH may also play a role in the effect of food in reducing ethanol bioavailability. Food, by delaying gastric emptying, allows for more extensive gastric metabolism.[123]

The accepted average rate of ethanol oxidation is 0.15 g/mL/hour for men and 0.18 g/mL/hour for women.[124] Although this rate still is widely used for both legal and medical purposes, other data suggest wide variability in ethanol metabolism. For example, wide differences in ADH activity have been demonstrated and attributed to heredity and other causes.[125,126] Chronic heavy drinkers frequently oxidize ethanol at twice the normal rates, with their metabolic rates returning to baseline after a period of abstinence.[127] The rate of oxidation in chronic heavy drinkers may also increase with elevated blood ethanol levels.[127] In contrast, patients with end-stage liver disease may progress to the point at which they have almost no metabolic capacity.

Chronic alcohol use is associated with characteristic changes in the liver. Hyperlipidemia and fat deposition in the liver occur because of shunting of the excess hydrogen into fatty acid synthesis and direct oxidation of ethanol for energy instead of body fat stores being used for energy. Fatty liver is the first step in a sequence of events that ultimately leads to alcoholic cirrhosis. Accumulated acetaldehyde, which interferes with mitochondrial function by shortening and thickening microtubules, has been implicated as playing a role in the hepatotoxic process. The damaged microtubules then inhibit the secretory functions of the hepatocytes, which results in an increase in size and weight of the liver.[128] Nutritional deficits and impaired hepatic protein metabolism may contribute as mechanisms of hepatotoxicity in chronic ethanol consumers.[129,130]

Acetaldehyde is believed to play a role in most actions of alcohol.[131] Elevated acetaldehyde concentrations during ethanol intoxication cause the commonly seen sensitivity reactions, including vasodilatation and facial flushing, increased skin temperature, increased heart and respiration rates, and lowered blood pressure. Acetaldehyde also contributes to the sensations of dry mouth and throat associated with bronchoconstriction and allergic-type reactions, as well as nausea and headache. These adverse effects mediated by acetaldehyde have the potential to protect drinkers against the excessive ingestion of alcohol, but acetaldehyde also has the potential to produce euphoric effects that may reinforce alcohol consumption.

Acetaldehyde also contributes to the increased incidence of GI and upper airway cancers that are seen with increased incidence in heavy consumers of alcohol and which may also play a role in the pathogenesis of liver cirrhosis.[132]

Ethanol ingestion can depress the CNS through all the different stages of anesthesia. Tolerance to this effect occurs after chronic use such that a blood ethanol level of 0.150 g/mL will not produce apparent behavioral or neurologic dysfunction in persons who drink a pint or more of 80-proof liquor (or its equivalent) daily for several years.

Neurobiological Basis of Alcohol Dependence

Proteins that are particularly sensitive to alcohol include ion channels, neurotransmitter receptors, and enzymes involved in signal transduction.[133] Notable neurotransmitters, hormones, and neuropeptides include adenosine, cannabinoid receptors, corticotropin-releasing factor (CRF), dopamine (DA), γ-aminobutyric acid (GABA), ghrelin, glutamate, neurokinin-1 (NK1), neuropeptide Y (NPY), norepinephrine, opioid peptides, and serotonin (5-HT). The key inhibitory neurotransmitter in the CNS is GABA, which is associated with a chloride-ion channel that is affected by low concentrations of alcohol. Normally, when GABA binds to the $GABA_A$ receptor, the chloride channel opens, allowing negatively charged chloride ions to enter the cell and inhibiting neuronal cell activity. In the presence of alcohol, GABA release accentuates the anxiolytic effect of both combined.[134] Receptor compensation for continual inhibition by alcohol is to reduce $GABA_A$ receptor subunits.[135] Other sedative medications, such as benzodiazepines, also bind to the chloride channel at slightly different sites and facilitate GABA inhibition. The existence of a common receptor mechanism for the actions of alcohol and sedative-hypnotics accounts for the cross-tolerance between these substances.

Glutamate is the major excitatory neurotransmitter in the CNS. Low doses of alcohol strongly inhibit NMDA receptors and inhibit neuronal activity.[136] After continual exposure to high doses of alcohol, NMDA receptors upregulate in an attempt to balance alcohol's inhibitory action. Thus, the combined effect of alcohol on $GABA_A$ and glutamate is to inhibit excitation and facilitate sedation.

Alcohol also affects several other ion channels and receptors. The 5-HT_3 receptor subtype is particularly sensitive to the action of low doses of alcohol, and may result in activation of 5-HT and DA. Alcohol also modifies the activity of β-adrenergic and adenosine neurotransmitter receptors linked to adenylate cyclase through membrane-bound G-proteins. Low doses of alcohol can facilitate the activity of norepinephrine, 5-HT, DA, endocannabinoid signaling system, and other neurotransmitter receptors linked to G-proteins.[137–139]

On a neurobiological behavioral level, the mesolimbic dopaminergic pathway from the ventral tegmental area to the nucleus accumbens is activated by most dependence-producing drugs, including alcohol, cocaine, opiates, and nicotine.[140,141] Putatively, activation of this pathway mediates drug reward and is responsible for the dependence-producing properties of all drugs of abuse.[142] Repeated alcohol use sensitizes the system, so that behavioral stimuli associated with alcohol also begin to release dopamine and to facilitate additional alcohol use.[143] Dopamine released by drugs of abuse are 2- to 10-fold that of natural rewards.[144] This sensitization may account for the craving and preoccupation with drugs of abuse.

Cessation of chronic alcohol use results in a withdrawal state of nervous system excitation that is dysphoric and negatively reinforcing. It has been suggested that abstinence contributes to alcohol craving and the preoccupation with alcohol use, in that dependent individuals will continue alcohol use to avoid this state.[145] As noted, chronic alcohol use causes $GABA_A$ downregulation and NMDA upregulation, leading to CNS hyperactivity. The locus coeruleus, a nucleus of norepinephrine-containing cells in the pons, becomes hyperactive during withdrawal, and is proposed as mediating some of the negative effects of withdrawal. Chronic alcohol and drug use alters gene expression and increases levels of adenylyl cyclase, upregulates cyclic adenosine monophosphate (cAMP)-dependent protein kinases, and activates cAMP-response element binding protein (CREB) and several phosphoproteins in this brain region mediating tolerance and dependence.[146]

ALCOHOL TOXICITY

Toxicology

In the medulla, ethanol can depress respirations by inhibiting the passive neuronal flux of sodium via a mechanism similar to that of general anesthetic agents.[147] The enzyme Na^+/K^+-adenosine triphosphatase (ATPase) is inhibited, cAMP concentrations are reduced, and GABA synthesis is impaired. Ethanol is a CNS depressant, and even the uninhibited behavior associated with its use is caused by preferential suppression of inhibitory neurons. More global neuronal inhibition is seen at high ethanol concentrations.

Treatment of alcohol intoxication is essentially supportive. In highly intoxicated patients, however, the prolonged slowing of the respiratory rate can lead to arrhythmias, cardiac arrest, and death, often accompanied by aspiration of vomitus. Respiratory depression is responsible for the respiratory acidosis acid–base abnormality. Even when blood ethanol levels are below those associated with medullary paralysis, a blunted respiratory response to hypercapnia and hypoxia is seen.[148,149] This makes the assessment of respiratory status a primary concern in severely intoxicated patients.

Highly intoxicated patients with depressed respiration require immediate supportive care that may include endotracheal intubation for respiratory support. This should be sufficient to restore acid–base balance to within normal limits. When metabolic acidosis is a significant component of the acid–base disturbance, it may be necessary to administer sodium bicarbonate. This should be done only in conjunction with appropriate respiratory support to prevent the development of hypercapnia.

Serum Ethanol Concentration

Chronic use of alcohol can produce significant tolerance; therefore, the BAL cannot be used as a sole determinant of physiologic status. By contrast, for the alcohol naïve, a BAC in the 0.30 mg% range can be fatal, although chronic drinkers can be awake and alert at even higher levels. The blood ethanol concentration generally correlates with the clinical presentation of the patient (Table 90-4), but tolerance varies among individuals. Impairment in motor function may become observable at levels of 0.05 mg%. Moderate motor impairment usually is seen at 0.08 mg%, which is the legal definition of intoxication in all states when driving. Respiratory depression may occur with ethanol concentrations 0.45 mg%.[150] The accepted median lethal dose (LD_{50}) for ethanol in humans is a blood concentration of 0.50 mg%, although fatalities have been reported with ethanol concentrations ranging from 0.295 to 0.699 mg%.[151,152]

Factors that may be associated with fatalities at lower ethanol concentrations include lack of tolerance to alcohol, ingestion of other drugs, heart disease, and pulmonary aspiration. For example, patients who died of combined ethanol and barbiturate ingestions had a mean ethanol concentration of only 0.359 mg%, a mechanism that is applicable to other more commonly used drugs that also depress respiration such as anxiolytics and opioids.[152,153] Therefore, the clinician should order a toxicologic urine screen to rule out possible concurrent drug ingestion.

Table 90-4

Relationship of Blood Alcohol Concentration to Clinical Status

Blood Ethanol Concentration	Clinical Presentation[a]
50 mg/dL (0.05 mg%)	Motor function impairment observable
80 mg/dL (0.08 mg%)	Moderate impairment; legal definition of intoxication in all states when driving
450 mg/dL (0.45 mg%)	Respiratory depression
500 mg/dL (0.50 mg%)	LD_{50} for ethanol

[a] Tolerance to alcohol varies among individuals.

LD_{50}, median lethal dose.

Acute Management

In the alert intoxicated patient, general management is supportive and protective. Volume depletion resulting in hypotension often occurs in ethanol-intoxicated patients. Hypothermia also is a complication of severe intoxication and can contribute to hypotension. Hypoglycemia most often occurs in conjunction with reduced carbohydrate intake. This situation is common in malnourished alcoholics but also might be particularly pronounced if a patient was dieting. If intravenous (IV) fluids are given, thiamine administration should precede that of glucose to prevent Wernicke's encephalopathy. Administration of a short-acting benzodiazepine, such as lorazepam, should be considered.

Gastric lavage may be useful if ingestion of other drugs is expected, or when the large consumption of alcohol is very recent. Activated charcoal absorbs ethanol poorly but should be administered when coingestion of other drugs is suspected. Hemodialysis rapidly removes ethanol from the body.[154] In uncomplicated cases, it has been suggested that dialysis be initiated immediately when the blood ethanol concentration is greater than 0.6 mg%.[151] Ventilatory assistance and good supportive care usually are most important because respiratory depression is the primary cause of death in ethanol intoxication. With good supportive care, dialysis is generally unnecessary. Dialysis may be considered if the patient cannot be stabilized or has other complicating factors, such as coexisting disease states (e.g., renal dysfunction) or ingestion of other drugs (Table 90-5).

ALCOHOL WITHDRAWAL

CASE 90-10

QUESTION 1: J.M. is a chef at a nursing home where his wife is the administrator. He drinks at work and was found unconscious and brought to the hospital. His wife states that J.M. regularly drinks half a gallon of vodka daily and has suffered an alcohol withdrawal seizure in the past. J.M.'s wife states that she does not believe that he ever abused street or prescription drugs. His blood alcohol concentration (BAC) on admission was 0.52 mg%. J.M. has a history of hepatic insufficiency secondary to cirrhosis. The following laboratory results are reported:

Sodium, 143 mEq/L	Albumin, 4.7 g/dL
Potassium, 4.2 mEq/L	Cholesterol, 423 mg/dL
CO_2, 25.2 mEq/L	CK, 1,344 units/L
Chloride, 107 mEq/L	Total bilirubin, 2.3 mg/dL
BUN, 18 mg/dL	Direct bilirubin, 0.3 mg/dL
Creatinine, 0.8 mg/dL	ALP, 74 units/L
Glucose, 101 mg/dL	AST, 288 units/L
Calcium, 9.9 mg/dL	ALT, 148 units/L

Magnesium, 0.9 mg/dL	GGT, 992 units/L
Uric acid, 6.3 mg/dL	

What signs and symptoms evident in a clinical diagnosis of alcohol withdrawal need to be monitored in J.M.?

Table 90-5

Acute Alcohol Intoxication: Symptoms and Treatment

Symptom	Course	Treatment
Respiratory acidosis	Alcohol-induced respiratory depression; blunted response to hypercapnia and hypoxia	Endotracheal intubation for respiratory support
Coma	Alcohol-induced CNS depression; ingestion of other drugs	Gastric lavage, naloxone (Narcan) 1 mg, repeat every 2–3 minutes up to 10 doses, depending on response and suspicion of ingestion. Dialysis possible
Hypotension	Hypovolemia	IV fluid replacement
Hypoglycemia	Most often occurs in malnourished patients. Pyruvate is converted to lactate, rather than glucose, through gluconeogenesis	50% glucose (50 mL) by IV push

CNS, central nervous system; IV, intravenous.

For many alcohol-dependent individuals with significant physical dependence, a cluster of withdrawal symptoms known as “alcohol withdrawal syndrome” (AWS) may occur on cessation or reduction of alcohol consumption. Depending directly on the degree of physical dependence, AWS can range from creating significant discomfort to mild tremor to alcohol withdrawal-related delirium, hallucinosis, seizures, and potentially death.[155,156] A gamma-glutamyl transferase (GGT) of 992 units/L in combination with the patient’s medical history suggests that J.M. is a heavy drinker. Although J.M.’s AST, ALT, and total bilirubin are elevated, his direct (unconjugated) bilirubin is within normal limits, suggesting a problem with bilirubin excretion as would be consistent with viral hepatitis or cirrhosis.

Patients may present with AWS in a variety of settings, because alcohol-dependent patients may be unrecognized and experience withdrawal after inpatient hospital admission for unrelated medical reasons. For example, a sample from a primary care practice indicated that 15% of patients presented with at-risk drinking patterns or identified alcohol-related problems.[157] Surgical patients should be screened preoperatively for possible alcohol dependence, to prevent and adequately treat AWS-related complications during and after surgery.[158]

Diagnosis requires cessation or reduction in alcohol use that has been heavy and prolonged, and two or more of the following symptoms developing within several hours to a few days after the cessation: autonomic hyperactivity, hand tremor, insomnia, nausea or vomiting, transient hallucinations or illusions (tactile, visual, or auditory), psychomotor agitation, anxiety, and generalized tonic–clonic seizures.[1] These symptoms must cause significant distress or impairment of important areas of functioning, and not be caused by a general medical condition or another mental disorder. Withdrawal-related seizure is considered a more severe manifestation of withdrawal, as is alcohol withdrawal delirium (AWD), or delirium tremens as it is traditionally called. AWD is estimated to have a mortality rate of approximately 5% of patients who go into alcohol withdrawal.[159] Recognized predictors for AWS complications include the duration of alcohol consumption, total number of prior detoxifications from alcohol, and previous withdrawal-related seizures and episodes of AWD.[160]

CASE 90-10, QUESTION 2: How could the severity of J.M.'s withdrawal symptoms be quantitatively assessed?

Of currently used instruments available for measuring the degree of withdrawal in an alcohol-dependent patient, the most commonly used is the revised Clinical Institute Withdrawal Assessment (CIWA-Ar). [161] Additionally the Sedation-Agitation Scale (SAS) could be used to assess agitation.[162] The CIWA-Ar is a validated ten-item scale used for grading severity of AWS that is often used as an inpatient assessment of withdrawal. The CIWA-Ar provides a final score with a maximum of 67 points assessing the extent of headache, nausea, tremors, agitation, paresthesia, sweats, audio and visual disturbances, and lack of awareness of time or location. Treatment of AWS can be initiated based on a patient's CIWA-Ar score. A CIWA-Ar rating of 8 points or less represents mild withdrawal and needs little pharmacologic support. A rating of 9 to 15 is associated with moderate withdrawal and may require some pharmacotherapy. A rating more than 15 corresponds to severe withdrawal, with an increased risk of seizures and AWD. Providers should also consider concomitant illnesses and medications when interpreting CIWA-Ar scores because individual items in the scale are not specific to AWS, and likewise some manifestations of withdrawal may be blunted. The SAS can be used in combination with the CIWA-Ar to evaluate the level of agitation and consciousness of a patient, and be linked to administer benzodiazepines on a symptom-triggered regimen when a patient becomes agitated (for scores >4 on a 7-point scale).

Management of withdrawal

CASE 90-10, QUESTION 3: What drugs are demonstrated to be the most clinically effective for alcohol withdrawal, particularly in a patient such as J.M. with evidence of cirrhosis?

Benzodiazepines

Benzodiazepines modulate anxiolysis by stimulating $GABA_A$ receptors and, in doing so, substitute pharmacologically for alcohol.[163] They are considered the drugs of choice for alcohol withdrawal,[158,163,164] long-acting benzodiazepines (e.g., chlordiazepoxide and diazepam) and short-acting agents (e.g., lorazepam and oxazepam) represent the most efficacious pharmacotherapies for the treatment of acute alcohol withdrawal.[157] They are effective in preventing both first seizures and subsequent seizures during alcohol withdrawal.[165] Longer-acting benzodiazepines may provide for easier weaning because they gradually self-taper on metabolism and excretion; this allows for less fluctuation in plasma drug levels.[166] Longer-acting benzodiazepines also cause fewer rebound effects and withdrawal seizures on discontinuation. Shorter-acting agents (e.g., lorazepam or oxazepam), which undergo phase II hepatic metabolism to inactive metabolites, require more frequent dosing but may be more appropriate for alcoholics with liver disease and the elderly.[164,167] When used appropriately, all benzodiazepines appear equally effective in ameliorating the signs and symptoms of alcohol withdrawal; however, the choice of a benzodiazepine is dependent on factors such as pharmacokinetic properties, dosage formulation, presence of liver impairment, and ease of dosage titration.[168] (Table 90-6)

Table 90-6

Suggested Treatment Strategies for Alcohol Withdrawal Syndrome

Protocol	Clinical Rationale	Drug	Dosing Regimen (Example)	Considerations
Fixed-Schedule Regimen	The patient receives a fixed dose of medication for 2–3 days regardless of the severity of symptoms. This approach is generally used in severe alcohol withdrawal.	Chlordiazepoxide	25 to 100 mg orally every 2–6 hours or 25 mg IV every 2–4 hours	Protocol fixed dose and time parameters are decided beforehand. Additional medication is provided as needed when symptoms are not controlled (e.g., the CIWA-Ar score remains at least 8–10).
		Diazepam	10 mg orally every 1–2 hours (maximum 60 mg) or 5–10 mg IV 20–	

			120 minutes (maximum 100 mg/hour or 250 mg/8 hour)	
		Lorazepam	On days 1 and 2 give 2–4 mg PO 4 times a day. On days 3 and 4 give 1–2 mg PO 4 times a day. On day 5 give 1 mg PO twice a day. May use IV or IM (maximum 20 mg/hour or 50 mg/8 hour).	
Symptom-Triggered Regimen	The patient is assessed every hour using the CIWA-Ar to determine the need for medication. The primary advantage of this approach is that less medication is used to achieve the same control and less sedation.	Chlordiazepoxide	50–100 mg	Less abuse potential for outpatients, low cost; long acting 24–48 hours.
		Diazepam	10–20 mg	Long duration of action (20–50 hours), which provides a smooth treatment course with less breakthrough symptoms.
		Lorazepam	2–4 mg	Shorter duration of action may be more appropriate for patients at risk for prolonged sedation (e.g., elderly, hepatic impairment).
Alternative Therapies	In patients with benzodiazepine allergy or when use of a benzodiazepine is deemed medically inappropriate.	Carbamazepine	Taper from 600–800 mg on day 1 down to 200 mg over 5 days. 400 mg PO TID for 3 days, then 400 mg PO BID for 1 day, then 400 mg PO for 1 day	Both carbamazepine and baclofen are nonaddicting. Few drug interactions. Cause relatively little cognitive impairment.
	May be equally efficacious as benzodiazepines.	Baclofen	5 mg PO TID for 3 days and then increase to 10 mg TID	Known to lower the seizure threshold; more information is needed before its routine use in alcohol withdrawal.

Adjunctive Therapies	Adrenergic hyperactivity	Clonidine	0.1 mg PO BID as needed	For mild to moderate hyperactivity.
	Adrenergic hyperactivity	β-Blockers: Atenolol Metoprolol	50 mg PO daily 2.5–5 mg IV	May improve vital signs faster than oxazepam alone. Up to 3 doses about 2 minutes apart; use parameters for HR and blood pressure.
	Agitation, hallucinations, delirium	Neuroleptics: Haloperidol Olanzapine	0.5–5 mg PO/IM/IV every hour; maximal dose 100 mg/day 10 mg IM	Rapid onset but note QTc prolongation (e.g., >450 ms); recommend baseline ECG before using IV. Maximal dosing, three 10-mg doses given 2–4 hours apart; monitor for orthostatic hypotension before the administration of repeated doses.

BID, 2 times daily; CIWA-Ar, Clinical Institute Withdrawal Assessment; ECG, electrocardiogram; HR, heart rate; IM, intramuscular; IV, intravenous; PO, oral; TID, 3 times daily.

An evidence-based guideline [published correction appears in Arch Intern Med. 2004;164:2068. Dosage error in article text]. Arch Intern Med. 2004;164:1405.

DOSE

Two strategies for dosing benzodiazepines in AWS include fixed-schedule and symptom-triggered regimens. Fixed-schedule regimens involve a set dose and interval for the agent chosen, which is to be tapered off at specific times, usually starting on the second day of treatment. Symptom-triggered regimens depend on the use of a rating scale of withdrawal severity, such as the CIWA-Ar previously noted, which is repeated at set intervals. Medication is only administered if the scoring from the scale is above a predetermined threshold value for treatment. In this way, the risk of undermedicating or overmedicating patients may be minimized, because the degree of withdrawal symptoms guides dosing. Several studies confirm that symptom-triggered regimens compared with fixed-dose regimens appear to result in a shorter duration of necessary therapy and less medication administered in total without any loss of efficacy.[168]

The treatment challenge associated with individuals who are in alcohol withdrawal with a comorbid medical illness is illustrated by the case of a patient with AWS who has coronary artery disease. Such a patient may be more aggressively treated for withdrawal-related hypertension and thus treated with a β-blocker or clonidine. The result of such adjuvant treatment may be a reduced sensitivity of the CIWA-Ar owing to a masking of the patient's autonomic manifestations of withdrawal. This could then lead to a higher likelihood of undermedicating the patient for withdrawal and may put the patient at higher risk for severe sequelae from withdrawal. Because of these exclusion criteria, the symptom-triggered approach has not been tested in such populations or those with histories of severe withdrawal including seizures or delirium. Therefore, traditional fixed-dose regimens are recommended in these populations.[168] An effective approach is most likely to consider combining these two dosing strategies. For example, a low-risk patient (no history of AWS or AWD, the patient consumes low weekly amounts of alcohol and has no signs or symptoms of early AWS) receives a symptom-triggered regimen (e.g., lorazepam 1 mg every hour as needed). Alternatively, a high-risk patient (history of AWS, AWD, or withdrawal seizures, consumes large daily amounts of alcohol, has signs or symptoms of early AWS) receives fixed-dose lorazepam or diazepam with a tapering dose schedule and as needed benzodiazepine administration for uncontrolled alcohol withdrawal signs or symptoms. Importantly, phenobarbital, dexmedetomidine and propofol are useful adjuncts to benzodiazepines if an inpatient has severe symptoms.[168]

CONTRAINDICATIONS, WARNINGS, AND INTERACTIONS

Elderly patients, those with hepatic or renal insufficiency, and those with medical (e.g., diabetes, cirrhosis) or other psychiatric illnesses (e.g., dementia) require close observation to prevent overmedication. As noted above, patients receiving calcium-channel blockers, β-blockers, and α_2-adrenergic agonists, some signs of withdrawal such as hypertension, tachycardia, and tremor may not be apparent.

Patients with a history of severe withdrawal symptoms, withdrawal seizures, or delirium tremens; multiple previous detoxifications; concomitant psychiatric or medical illness; recent high levels of alcohol consumption; pregnancy; and lack of a reliable support network should be considered for inpatient treatment regardless of the severity of their symptoms.[168]

Lorazepam is the only benzodiazepine with predictable intramuscular absorption (if intramuscular administration is necessary). Rarely, it is necessary to use extremely high dosages of benzodiazepines to control the symptoms of alcohol withdrawal. Controlled studies comparing the advantages and disadvantages of the various benzodiazepines in alcohol detoxification have not been performed, and no evidence exists to definitively support the use of lorazepam as the first-line agent in the treatment of AWS.[168,169]

In most patients with mild to moderate withdrawal symptoms, outpatient detoxification is safe and effective, and costs less than inpatient treatment. If outpatient treatment is chosen, the patient and support person(s) should be instructed on how to take the prescribed medication, its side effects, the expected withdrawal symptoms, and what to do if symptoms worsen. Small quantities of the withdrawal medication, especially benzodiazepines, should be prescribed at each visit. Because close monitoring is not available in outpatient treatment, a fixed-schedule regimen should be used.

Given J.M.'s elevated liver enzymes, a reasonable approach would be to start with lorazepam. Shorter-acting agents, such as lorazepam, which do not undergo extensive hepatic metabolism, are more appropriate for patients with evidence of hepatic insufficiency.

ADJUNCTIVE TREATMENTS

CASE 90-10, QUESTION 4: What adjunctive therapeutic support might be considered for J.M.?

The hydration, electrolyte (especially potassium and magnesium), and nutritional status of patients should be assessed at presentation. Support with IV fluids may be necessary in those patients with excessive losses through vomiting, sweating, and hyperthermia.[170] Thiamine and multivitamins as well as folate 1mg should be routinely administered to patients in alcohol withdrawal. If IV fluids are given, to prevent precipitation of Wernicke encephalopathy thiamine administration should precede that of glucose.[160] Alcohol-dependent patients are deficient of thiamine and have a higher risk for developing Wernicke encephalopathy.[171] The condition is a triad of acute mental confusion, ataxia, and ophthalmoplegia. Korsakoff amnestic syndrome is a late neuropsychiatric manifestation of Wernicke encephalopathy with memory loss and confabulation; hence, the condition is referred to as Wernicke–Korsakoff syndrome. It is most often seen in chronic alcohol use disorder patients, but it can also be seen in disorders associated with malnutrition, e.g., long-term hemodialysis or patients with acquired immunodeficiency syndrome (AIDS).[172]

Thiamine deficiency results in a decrease in cerebral glucose utilization. The body usually stores about 3 weeks of thiamine with daily requirements of about 1.5 mg. Rapid correction of brain thiamine deficiency can occur with high plasma concentrations of thiamine, achieved by parenteral supplementation only because absorption of the oral thiamine by the GI tract is minimal (<5%), even with massive oral daily dosing.[171] Patients should receive at least 200-500mg TID IV for 3 days to prevent the neuropsychiatric effects of thiamine deficiency.[172]

Several adjunctive medications, aside from the sedative-hypnotics, may serve ancillary roles in the therapy of AWS. Their selection should be based on treating specific symptoms associated with the syndrome. For instance, β-blockers (propranolol,[173] atenolol[174]) or α_2-adrenergic agonists (e.g., clonidine[175] or dexmedetomidine if in an ICU) can be used for moderate to severe hypertension or other autonomic manifestations. α_2-adrenergic agonists are preferred because it reduces NE outflow from the nerve and addresses all hyperadrenergic effects instead of just effecting the β receptors with a β-blocker, and delirium seems to be more common with the β-blocker use.[168,169] Antipsychotics (e.g., haloperidol, quetiapine) can be used for managing hallucinations and severe agitation, but care must be used because these drugs can reduce the seizure threshold.[163,168,176]

PHARMACOTHERAPY OF ALCOHOL DEPENDENCE

CASE 90-11

QUESTION 1: R.M. is a 55-year-old man, weighing 140 lb, who used to drink about 60 drinks a week before going through alcohol detoxification. R.M. is married and has a good job, and he is now committed to remain alcohol abstinent. R.M. heard about a drug called disulfiram from a friend and is interested in using this medication to help him abstain from drinking. Laboratory values obtained today include the following:

Sodium, 132 mEq/L	AST, 30 units/L
Potassium, 3.3 mEq/L	ALT, 35 units/L
CO_2, 22.6 mEq/mL	Uric acid, 9.1 mg/dL
Chloride, 109 mEq/L	Calcium, 8.7 mg/dL
BUN, 14 mg/dL	Magnesium, 1.7 mg/dL
Creatinine, 1.0 mg/dL	Albumin, 4.0 g/dL
Glucose, 123 mg/dL	Cholesterol, 255 mg/dL
Total bilirubin, 0.3 mg/dL	CK, 78 units/L
Direct bilirubin, 0.1 mg/dL	GGT, 30 units/L
ALP, 53 units/L	

Is disulfiram an appropriate agent to consider for R.M.?

In order to assess alcohol use disorder treatments an accurate medical history, including laboratory test results. In addition, several instruments are available to screen and delineate the extent of a patient's alcohol use. Ultimately, time and purpose for use are always major factors when deciding which instrument to use. The simplest screen to assess risk of alcohol abuse is to ask the patient, during the past year on how many occasions have you had five or more drinks (for a man) or four or more drinks (for a woman) at one time?[177] An affirmative answer would suggest that further follow-up of the patient's alcohol use history is needed. A second tool called the **C-A-G-E** consists of four questions: (1) Have you ever felt you should **c**ut down on your drinking?; (2) Have people **a**nnoyed you by criticizing your drinking?; (3) Have you ever felt bad or **g**uilty about your drinking?; and (4) Have you ever felt you needed a drink first thing in the morning to steady your nerves or get rid of a hangover (**e**ye opener)? Positive responses to two questions suggest an alcohol problem (Table 90-7).[178] The Alcohol Use Disorders Identification Test (AUDIT), which was developed by the World Health Organization, has also been shown to be effective in screening individuals and distinguishing problem drinkers from others.[179]

Pharmacotherapy

The pharmacologic treatments of alcohol dependence focus on relapse prevention once detoxification is complete and the patient has achieved a few days of abstinence. Treatment is intended to be an adjunct to psychosocial treatments and not used alone.[180] To date, disulfiram, acamprosate, and naltrexone tablet and injection have been FDA-approved for the treatment of alcohol dependence. In addition, several other drugs have shown varying degrees of success such as quetiapine, ondansetron, and others. [180–202] Yet much is still unknown about the long-term rates of abstinence, how long these drugs should be used once patients are in treatment, the optimal doses, and whether the drugs are more effective in men or women or for which specific subpopulations.[203]

DISULFIRAM

Table 90-7

Useful Screens for Assessing Alcohol Problems

The C-A-G-E Screening Questions (CAGE)
Have you ever felt you should cut down on your drinking? Have other people annoyed you by criticizing your drinking?
Have you ever felt guilty about drinking?
Have you ever taken a drink in the morning to calm your nerves or get rid of a hangover (eye opener)?
Methods for Determining Recent Alcohol Consumption
Acute consumption ■ Blood alcohol concentration ■ Urine (ethyl glucuronide) ■ Saliva ■ Breath alcohol concentration
Recent heavy consumption

- Gamma-glutamyl transferase (GGT)
- Carbohydrate-deficient transferrin (CDT)
- Mean corpuscular volume (MCV)

Disulfiram is an irreversible acetaldehyde dehydrogenase inhibitor that blocks alcohol metabolism, leading to an accumulation of acetaldehyde. Disulfiram reinforces an individual's desire to stop drinking by providing a disincentive associated with increased acetaldehyde levels, resulting in headache, palpitations, hypotension, flushing, nausea, and vomiting when patients consume alcohol. The primary predictor of success with disulfiram is the patient's commitment to total abstinence from alcohol. Although anecdotal reports of success are common, clinical evidence suggests disulfiram appears to be most effective for alcoholics who are involved in special high-risk situations (e.g., weddings, graduations) and is particularly effective when administration is supervised.[3,180]

Controlled clinical trials of disulfiram have clearly shown efficacy, yet this has not been a consistent finding.[180] Double-blind, placebo-controlled studies using disulfiram are difficult because the psychological deterrent to use alcohol is experienced by both treatment groups and those who relapse will be unblinded when they experience the pharmacologic interaction.

In the most rigorous clinical trial conducted in a population of veterans, no significant difference in abstinence rates was demonstrated between patients taking placebo or 1 mg or 250 mg of disulfiram.[181] Patients randomly assigned to receive 250 mg of disulfiram daily drank less frequently (significantly fewer drinking days per year), however. Patients who were middle-aged and had social stability were more likely to benefit from disulfiram. In another trial in which administration was supervised, patients receiving disulfiram drank less alcohol and less frequently; however, on randomization, patients were unblinded to their drug.[204]

The efficacy of disulfiram compared with acamprosate and naltrexone shows definitive efficacy advantage for disulfiram when the patients are assigned to supportive care that verifies adherence.[205,206] Although no advantage was seen for combining disulfiram with naltrexone in dually diagnosed alcohol-dependent patients.[207] In one study, disulfiram combined with acamprosate resulted in increased days of cumulative abstinence.[208]

Dosing

The recommended starting dose of disulfiram is 250 mg once daily, with a range of 125 to 500 mg/day.[207] If a patient drinks

---

and does not experience a disulfiram–ethanol reaction, the dose can be increased to 500 mg, because a significant proportion of patients may not experience a disulfiram–alcohol reaction at the usual 250-mg daily dose.[209,210] Side effects are increased, however, at doses exceeding 250 mg. Dosing starts at least 12 to 24 hours after abstinence initiation (when the blood or breath alcohol concentration is zero). Treatment continues, depending on the particular needs of the individual, but is generally at least 90 days, and maintenance therapy may be required for years.

Contraindications, Warnings, and Interactions

Because of the intense cardiovascular and physical changes that occur in the disulfiram–ethanol interaction, disulfiram is contraindicated in patients with cardiac disease, coronary occlusion, cerebrovascular disease, and renal or hepatic failure. At somewhat higher doses, psychotic reactions have occurred. It is not definitive that disulfiram causes fetal abnormalities when administered during pregnancy but some data are found regarding limb reduction anomalies in infants born to disulfiram-treated mothers taking disulfiram during the first trimester of pregnancy.[211,212] Thus, disulfiram should only be used during pregnancy if the expected benefit to the mother and fetus is greater than the possible risk to the fetus; however, it should be avoided in the first trimester (category C). No information is available about the safety of this medicine during breast-feeding.

Disulfiram can also be hepatotoxic and should be used cautiously in patients with liver disease. Liver function should be established at baseline and after 14 days of treatment, and a complete blood count (CBC) and liver function tests (LFTs) should be obtained every 6 months.[213]

R.M. has normal hepatic function; however, LFTs should be monitored at baseline and periodically during treatment. Although not all clinicians agree, most would recommend—at minimum—baseline LFTs: ALT, AST, and GGT and withholding disulfiram when LFTs are more than three times upper limits of normal.[213] If elevated, repeat LFTs every 1 to 2 weeks until normal, and then every 3 to 6 months if no elevations, with an awareness that increased LFT results may signal a return to drinking rather than disulfiram toxicity.[214,215] Persistently elevated LFTs may also indicate viral hepatitis (B or C), for which alcoholics have a higher risk, and thus the need to order a hepatitis profile. Currently, guidelines point out that a reduction in alcohol use will lead to more normalized LFTs. Psychiatric adverse effects include disorientation, agitation, depression, and behavioral changes such as paranoia, withdrawal and bizarre behaviors, and worsening of schizophrenia, especially at doses greater than 250 mg daily.[216,217] Disulfiram should be avoided or used very cautiously in persons with these conditions although it can be used safely at a dose of 250 mg daily in alcohol-dependent patients with concomitant psychiatric disorders, including schizophrenia.[207,218,219] Common side effects of disulfiram include drowsiness, particularly in the first few weeks of treatment, a metallic or garlic taste, and sexual dysfunction. The dose can be taken at bedtime if drowsiness or tiredness occurs.

Disulfiram is a potent inhibitor of the CYP2E1 oxidase and can interact with anticoagulants (warfarin), antiepileptics (phenytoin, carbamazepine), some benzodiazepines (e.g., diazepam), and tricyclic antidepressants (amitriptyline, desipramine), potentially increasing the toxicity of these medications. Delirium can result in combination with monoamine oxidase inhibitors. Adverse effects with disulfiram that mimic the alcohol–disulfiram interaction can also occur with metronidazole and omeprazole.[220]

To receive optimal results with disulfiram, patients must receive regular counseling and be closely monitored for any changes in hepatic function. Having someone participate in helping to validate the administration process is known to lead to better outcomes. Discontinuation of disulfiram should occur only after consultation with the prescriber and counselor involved. Patients must stop the medication for at least 3 days (up to 14 days in some) before being exposed to products containing alcohol. It is important to educate patients taking disulfiram about the dangers of consuming even small amounts of alcohol in foods, over-the-counter medications, mouthwashes, and topical lotions. The patient should report any respiratory difficulty, nausea, vomiting, decreased appetite, dark colored urine, or a change in pigmentation in the skin or eyes (primarily yellowing).

Summary

Generally, given the special circumstances needed for success, disulfiram is not the drug of choice for treating alcoholism. The social, medical, and psychiatric status of a candidate is an important consideration in the use of disulfiram. R.M. would appear to be a reasonable candidate for disulfiram given he has agreed to have his medication administration supervised (in this case by his wife), his steady employment, and his motivation to sustain abstinence. R.M. should also receive counseling and support services on a regular basis.

ACAMPROSATE

Acamprosate (Campral) has multiple actions, but is principally a glutamate and GABA modulator. The key mechanism of action is considered to be as a weak functional antagonist of the glutamate NMDA receptor, possibly mediated through indirect modulation of the receptor site via antagonism at the mGluR5 receptor.[221] A series of meta-analyses and systematic reviews demonstrated that when used as an adjunct to psychosocial interventions, acamprosate improves drinking outcomes such as the length and rate of abstinence.[180,222–224] This effect is less likely if acamprosate is not initiated quickly after a detoxification.[225,226] Evidence indicates that the effect of acamprosate on abstinence lasts after the treatment is stopped.[227] Acamprosate appears to be especially useful in a therapeutic regimen targeted at promoting abstinence and can be used in primary care settings as well as specialized addiction treatment programs.[228] Few contraindications to treatment exist. Little consistent information is found about patient characteristics that predict improvement while taking acamprosate. In a meta-analysis of all US and European studies, predictors of abstinence were motivation, readiness to change, baseline abstinence, initial first week compliance, and living with a partner or child.[229] A pooled analysis of seven European trials, however, found no significant predictors of the abstinence outcome measures.[230] Candidates for acamprosate should be committed to abstinence and begin the medication after being abstinent from alcohol.[231,232]

In a systematic review of the efficacy data related to acamprosate, proof for efficacy of acamprosate was strong.[231] Moreover, several acamprosate studies have reported positive results. For example, in a study of 272 severely dependent alcoholics, patients receiving acamprosate showed a significantly higher continuous abstinence rate within the first 2 months of treatment compared with patients receiving placebo.[184] Of acamprosate-treated patients, 40% were continuously abstinent for a 48-week period compared with 17% of those who received placebo.

Acamprosate has also been studied for periods of up to a year. In a long-term follow-up (12 months) after trial completion, acamprosate still maintained an effect on abstinence rates, but not on nondrinking days. Some studies have found limited to no efficacy,[191,233–236] although two of the studies may have been underpowered.[191,233–236] One of these studies also had a short treatment period, and the other had a long delay in initiating treatment.[234,235] In summary, most studies suggest that acamprosate is a safe and well-tolerated drug for the promotion of alcohol abstinence.[237]

Dose

Acamprosate is dispensed in 333-mg tablets and the usual dose is 666 mg/day 3 times daily.[238] Patients can be started on the full dose without titration. Acamprosate is not well absorbed from the GI tract and with a terminal half-life of around 30 hours it takes several days to achieve desired blood levels of the medication.[238] The medication appears to be safe and effective in alcoholics, with minimal side effects. It does not appear to produce sedation and does not cause drug dependence. Main adverse effects of acamprosate appear to be GI, including nausea, diarrhea, and bloating. Nausea or diarrhea can be easily managed, but if symptoms are severe or persistent, the dose should be reduced by one-third to one-half. The duration of therapy ultimately depends on treatment success and the willingness of the patient to continue therapy indefinitely.

Contraindications, Warnings, and Interactions

Acamprosate is excreted unchanged in the urine and should not be used in patients with impaired kidney function (creatinine clearance [CrCl] <30 mL/minute) or in patients who previously exhibited hypersensitivity to acamprosate.[238] The dose should be 333 mg 3 times daily in patients with moderate renal impairment (CrCl 30–50 mL/minute). Acamprosate should only be used during pregnancy when the benefit clearly outweighs the risk as the drug has been shown to be teratogenic (category C) in rats.[238] Tetracyclines may be inactivated by the calcium component in acamprosate during concurrent administration.[238] Naltrexone increases plasma levels of acamprosate, although the clinical significance of this interaction is unknown and the two can be safely used together.[238,239] Suicidal ideation and attempted and completed suicides have occurred in patients taking acamprosate.

Acamprosate must be used in combination with a psychosocial program such as cognitive-behavioral therapy (CBT) or regular Alcoholics Anonymous (AA) meetings. Acamprosate may be taken without regard to meals. The tablets should not be crushed and should be taken whole. Although no interaction with alcohol occurs, abstinence in combination with counseling and social support is required to attain optimal treatment. Patients should report persistent diarrhea, sudden or excessive weight gain, swelling of the extremities, respiratory difficulties, fainting, or thoughts of suicide.

A retrospective long-term study in 353 alcohol-dependent patients, supervised disulfiram was found to be superior to acamprosate, particularly in patients with a long history of alcohol dependence.[206]

NALTREXONE

Naltrexone blocks the action of endorphins when alcohol is consumed, and this results in an attenuation of the dopamine release at the nucleus accumbens thought to be crucially important to positive reinforcement, reward, and craving.[145] Although naltrexone therapy has been recommended for all alcohol-dependent patients who do not have a medical contraindication to its use, a survey of 1,388 US physicians specializing in addiction reported that they prescribed naltrexone to an average of only 13% of their patients.[240] The main self-reported reasons why physicians did not prescribe naltrexone to more patients were that patients refused to take the medication or comply with prescribing regimens (23%), and that patients could not afford the medication (21%).

Evidence seems to support the use of naltrexone as an adjunct to psychosocial interventions, with higher abstinence rates in short-term treatment, and as a deterrent to progressing from a lapse to a full-blown relapse.[180,209,241,242] Naltrexone is as efficacious as disulfiram and probably more efficacious than acamprosate.[191,242–244]

Several studies indicate that naltrexone is most effective in patients with strong craving,[182,245] poor cognitive status at study entry,[246] and high compliance.[247,248] This observation is consistent with the demonstrated effect of naltrexone in reducing craving. Evidence also indicates that persons with a family history for alcoholism, early age at onset of drinking, and comorbid use of other drugs are more likely to benefit from naltrexone.[249]

Comprehensive reviews of pharmacotherapies for alcoholism concluded that oral naltrexone produced a consistent decrease in the relapse rate to heavy drinking and in drinking frequency, although it did not enhance absolute abstinence rates.[232,250,251] More specifically, several studies using naltrexone report the opioid antagonist to be more effective than placebo in reducing relapse rates, in increasing the percent of nondrinking days,[182,183,247] and in reducing craving in heavy drinkers.[252] Yet other studies fail to demonstrate a significant difference with placebo.[253,254] Several factors may explain the discrepancies in results of the different clinical trials with naltrexone. Many of the studies included small sample sizes and may lack the statistical power to demonstrate treatment effects.[235] Several large sufficiently powered studies also reported negative results.[253–255]

The COMBINE trial[191] clearly supports the effectiveness of naltrexone in that each of the groups of patients receiving naltrexone in conjunction with medical management had a higher percentage of days abstinent than those receiving placebo plus medical management without naltrexone or combined behavioral intervention (CBI). Naltrexone also reduced the risk of heavy drinking. Extended-release naltrexone injection 380 mg is safe and well tolerated in alcohol-dependent individuals.[256] In two double-blind, randomized, placebo-controlled trials, the efficacy of once-monthly extended-release injectable or depot forms of naltrexone was demonstrated.[198,257,258] which suggests the advantage of increased compliance. Garbutt et al.[198] reported that men receiving naltrexone injection had significantly better treatment outcomes than women, and women who received naltrexone demonstrated no difference from those who received placebo. Additionally, because a robust effect was seen for naltrexone injection compared with placebo for people coming into the study abstinent, the FDA required the manufacturer to place a requirement for abstinence when starting the medication on its product information. In the primary care setting, naltrexone injection given for 3 months and offered with physician-delivered medical management was found to be effective in the treatment of alcohol dependence.[259]

Dose

Naltrexone has been approved for use in the first 90 days of abstinence when the risk of relapse is highest. It has also been shown to be safe and well tolerated by patients for periods of up to a year. Treatment with naltrexone should continue based on the response to the medication. Discontinuation should only be considered in consultation with the health care provider. The usual dose of naltrexone is 50 mg daily, although doses of 25 mg to 100 mg daily have been reported to be effective, particularly in those with lower blood concentrations of the drug.[259] Side effects, such as nausea or headache, are more common in the initial few days of therapy. Starting with a 25-mg dose (half a tablet) for the first two to four daily doses may reduce the incidence of side effects. Because of its long half-life (4 hours, or 13 hours for 6-β-naltrexol, naltrexone's active metabolite), naltrexone has been studied as three times weekly doses of 100 mg on Mondays, 100 mg on Wednesdays, and 150 mg on Fridays (or the equivalent of 50 mg daily).[202] This method may facilitate supervised or observed administration of naltrexone, because only three (versus seven) observations are required per week. However, this schedule is not recommended for most cases.

The extended-release injection (380 mg) should be administered by deep IM injection every 4 weeks deep into a gluteal muscle, alternating buttocks each injection. No dose adjustment is required for mild or moderate renal or hepatic impairment, but naltrexone has not been studied in severe renal or hepatic impairment.[198]

Contraindications, Warnings, and Interactions

Naltrexone is contraindicated in patients with a history of sensitivity to naltrexone with acute hepatitis or liver failure; in those who are physically dependent on opioids, receiving opioid analgesics, or in acute opioid withdrawal. The benefit of using naltrexone during pregnancy should clearly outweigh the risk. The concurrent administration of naltrexone and opioid analgesics is contraindicated. To avoid triggering an acute abstinence syndrome, patients must be opioid free for a minimum of 7 to 14 days before initiating treatment with naltrexone, as substantiated with a urine drug test. Although rarely performed, a naloxone challenge test can be used before treatment with naltrexone to rule out concurrent use of opioids. Naltrexone is in the FDA pregnancy category C, and it is unknown whether naltrexone passes into breast milk.

A possible clinical concern with naltrexone tablets or long-acting injectable naltrexone is pain management. Any attempt to overcome the opioid blockade produced by naltrexone using exogenous opioids may result in fatal overdose. Should a patient be in pain after receiving an injection, the first drug of choice should be a nonopioid, such as a nonsteroidal anti-inflammatory drug (NSAID). If the patient is still in pain, an opiate can be used, but it will most likely have to be administered in a higher dose and more frequently. When reversal of naltrexone blockade is required for pain management, patients should be monitored in a setting equipped and staffed for cardiopulmonary resuscitation and monitored for signs of respiratory depression.

In a yearlong safety study, the most common side effects were nausea, dizziness, sedation, headache, anxiety, and blurred vision.[260] Should such side effects occur, reducing the dosage by one-half often reduces the side effects. Large doses (e.g., 200 mg) of naltrexone can cause liver failure. Patients should report excessive tiredness, unusual bleeding or bruising, loss of appetite, pain in the upper right part of the stomach, any discoloration of the skin or eyes, a change in stool color or urine, thoughts of suicide, or signs of pneumonia. Patients receiving extended-release naltrexone injection must also monitor the injection site for any type of reaction, e.g., swelling, tenderness, bruising, or redness-69% for naltrexone v 50% for placebo). Reactions that do not resolve in 2 weeks may result in induration, cellulitis, abscess, sterile abscess, or necrosis. Some patients may need to be evaluated for surgical intervention.[260]

COMBINATION PHARMACOTHERAPY

The rationale for combining medications is that acamprosate reduces negative reinforcement and naltrexone attenuates positive reinforcement.[141] To test this hypothesis, a randomized, controlled study of 160 patients performed in Europe demonstrated that although combining naltrexone and acamprosate was more effective than either placebo or acamprosate alone, adding acamprosate was not significantly more effective than naltrexone alone.[244] In the much larger study, the COMBINE trial randomized more than 1,300 individuals in a double-blind fashion to receive placebo, naltrexone, or acamprosate alone or in combination with medical management or CBI.[191] Results from this study suggest that acamprosate has no significant effect on drinking versus placebo, either by itself or with any combination of the other treatments in the study. Furthermore, patients receiving placebo and medical management (MM) from a health care professional had better outcomes than patients receiving CBI (a CBT-like therapy that includes 12-step facilitation) alone. From the available evidence, it is acceptable to combine acamprosate with naltrexone with the expectation that in some patients it may not be any more effective than naltrexone alone.

Topiramate

Topiramate has multiple mechanisms of action, including enhanced $GABA_A$ inhibition that results in decreased dopamine facilitation in the midbrain, thought to be of potential benefit in the treatment of alcohol use disorder, maintenance treatment.[261] Additionally, it causes antagonism of kainate to activate the kainate/AMPA glutamate receptor subtypes and inhibition of type II and IV carbonic anhydrase isoenzymes.[262] Topiramate is not FDA-approved for the treatment of alcohol use disorder.

A randomized, double-blind, placebo-controlled trial used an escalating dose from 25 to 300 mg/day of topiramate or matching placebo in 150 alcohol-dependent men and women during the first 8 weeks of a 12-week period.[190] Patients stayed at the same dose for the last 4 weeks of the study. All patients in the study received brief behavioral compliance enhancement therapy (BBCET) that was a 10- to 15-minute meeting with a health care professional that focused on resolving side effect issues and facilitated adherence. Participants receiving topiramate reported significantly fewer drinks per day and drinks per drinking day, significantly fewer drinking days, significantly more days of abstinence, and significantly less craving than those on placebo. The evidence suggests that although abstinence was not a goal at the start of the topiramate study, the medication may be more beneficial during the abstinence initiation phase of treatment.[263] In a phase II clinical trial, the use of topiramate for alcohol dependence treatment was confirmed by outcomes demonstrating that topiramate recipients showed a significantly greater lowering of percentage of heavy drinking days and drinks per drinking day, and a higher percentage of days abstinent.

In the treatment of alcohol dependence, topiramate is titrated from 25 mg/day up to 300 mg/day over a 6-week period (100 mg in the morning; 200 mg in the afternoon) or to the patient’s maximal tolerable dose. Abrupt discontinuation of topiramate has been associated with seizures in patients without a history of seizures, and for this reason, gradual withdrawal of the drug (e.g., a 25% decrease in the dosage every 4 days for 16 days) is recommended.

In addition to paresthesias (tingling in the extremities), other prominent side effects include mental confusion, slowness in thinking, depression, and somnolence, which may be attenuated by titration when initiating therapy, and the development of renal calculi in about 1.5% of patients.[264] Adequate hydration is encouraged, particularly in patients who may be at risk for developing calculi. Topiramate can cause drowsiness, dizziness, changes in memory, a change in taste (particularly with carbonated beverages), vision changes (particularly associated with increased intraocular pressure), pressure to the touch, loss of appetite or weight loss, and sudden changes in mood.

CONTRAINDICATIONS, WARNINGS, AND INTERACTIONS

Topiramate is contraindicated in those hypersensitive to the drug. Topiramate should be used with caution in those who have a history of urolithiasis, paresthesias, secondary angle closure glaucoma, renal or hepatic impairment, and conditions or therapies that predispose to acidosis (e.g., renal disease, severe respiratory disorders, status epilepticus, diarrhea, surgery, ketogenic diet, or drugs). Monitoring for hyperchloremic non–ionic-gap metabolic acidosis is essential, and therefore baseline chemistry (e.g., HCO_3^- and pH) should be assessed and monitored regularly thereafter. Metabolic acidosis can cause symptoms such as tiredness and loss of appetite, or more serious conditions including arrhythmia or coma. Topiramate has been found to be teratogenic in animal studies and is a pregnancy category C medication.[264]

Concomitant use of oral contraceptives, phenytoin, carbamazepine, and valproic acid has been found to interact with topiramate.[220] Coadministration of another carbonic anhydrase inhibitor, such as acetazolamide, may increase the possibility of renal stone formation and should be avoided.

COMORBIDITIES IN ALCOHOL USE DISORDER

It is quite common for patients who are involved in harmful drinking to have comorbid medical issues. Alcohol has significant drug interactions with many medications (Table 90-8). Clinicians must also consider the potential for comorbid psychiatric disorders, (also known as dual diagnosis, e.g., depression, bipolar disorder, or schizophrenia) combined with a substance use disorders. Tobacco and caffeine dependence are common.[265] Increased comorbid conditions lead to a poorer treatment prognosis for both medical and psychiatric conditions.

p. 1901

p. 1902

Table 90-8

Ethanol–Drug Interactions

Acetaminophen	Chronic excessive alcohol consumption increases susceptibility to acetaminophen-induced hepatotoxicity. Acute intoxication theoretically protects against acetaminophen toxicity because less hepatotoxic metabolite is generated.
Anticoagulants (oral)	Chronic ethanol consumption induces hepatic metabolism of warfarin, decreasing hypoprothrombinemic effect. Very large acute ethanol doses (>3 drinks/day) may impair the metabolism of warfarin and increase hypothrombinemic effect. Vitamin K-dependent clotting factors may be reduced in alcoholics with liver disease, also affecting coagulation.
Antidepressants	Enhanced sedative effects of alcohol and psychomotor impairment are possible. Acute ethanol impairs metabolism. Fluoxetine, paroxetine, fluvoxamine, and probably other serotonin reuptake inhibitors (SSRIs) do not interfere with psychomotor or subjective effects of ethanol.

Ascorbic acid	Ascorbic acid increases ethanol clearance and serum triglyceride levels and improves motor coordination and color discrimination after ethanol consumption.
Barbiturates	Phenobarbital decreases blood ethanol concentration; acute intoxication inhibits pentobarbital metabolism; chronic intoxication enhances hepatic pentobarbital metabolism.
Benzodiazepines	Psychomotor impairment increases with the combination.
Bromocriptine	Ethanol increases gastrointestinal side effects of bromocriptine.
Caffeine	Caffeine has no effect on ethanol-induced psychomotor impairment.
Calcium-channel blockers	Verapamil inhibits ethanol metabolism and increases intoxication.
Cephalosporin antibiotics	Ethanol produces flushing, nausea, headaches, tachycardia, and hypotension. Cephalosporin antibiotics that have an ethyl tetrazole thiol side chain produce this disulfiram-like reaction (e.g., cefoperazone, cefamandole, cefotetan).
Chloral hydrate	Elevation of plasma trichloroethanol (a chloral hydrate metabolite) and blood ethanol may occur. Combined central nervous system (CNS) depression. Vasodilation, tachycardia, headache.
Chloroform	Ethanol increases chloroform hepatotoxicity.
Doxycycline	Chronic consumption of ethanol induces hepatic metabolism of doxycycline and may lower serum concentration of the antibiotic.
Erythromycin	Ethanol may interfere with absorption of the ethylsuccinate salt. Effects on other formulations are unknown.
Furazolidone	When ethanol is ingested, nausea, flushing, light-headedness, and dyspnea may occur (i.e., a disulfiram-like reaction).
H_2 antagonists	Cimetidine potentiates ethanol effects. Increases peak plasma ethanol concentrations and area under the plasma ethanol concentration–time curve. CNS toxicity from increased cimetidine serum concentration. Nizatidine and ranitidine may also increase blood alcohol levels (BALs) slightly by inhibiting gastric alcohol dehydrogenase. Famotidine does not affect BALs.
Isoniazid	Consumption of ethanol with isoniazid increases risk of hepatotoxicity. Tyramine-containing alcoholic beverages may cause hypertensive reaction.
Ketoconazole and metronidazole	When ethanol is ingested, nausea, flushing, light-headedness, and dyspnea may occur (i.e., a disulfiram-like reaction may occur with metronidazole). A sunburn-like rash has been reported with ethanol consumption and ketoconazole. A similar reaction may occur with itraconazole, although no reports exist.
Meprobamate	Synergistic CNS depression may occur.
Metoclopramide	Enhances sedative effects of ethanol.
Monoamine oxidase inhibitors	Tyramine-containing alcoholic beverages (e.g., wines, beer) may cause a hypertensive crisis. Pargyline may inhibit aldehyde dehydrogenase and cause a disulfiram-like interaction with ethanol.
Narcotic analgesics	Volume of distribution of intravenous meperidine increases with increasing ethanol consumption. Clinical significance unknown. Potential for enhanced CNS depression.
Oral hypoglycemic agents	Chlorpropamide, tolbutamide, and tolazamide may cause flushing, light-headedness, nausea, and dyspnea if alcohol is ingested (i.e., a disulfiram-like reaction).
Paraldehyde	Possible metabolic acidosis may occur.
Phenothiazines	Potentiates psychomotor effects of ethanol.
Quinacrine	Possibly inhibits acetaldehyde oxidation.
Salicylates	Increases gastric bleeding associated with aspirin; may increase chance of gastrointestinal hemorrhage.
Tetrachloroethylene	Combined CNS depression may occur.

Trichloroethylene	Flushing, lacrimation, blurred vision, and tachypnea may occur when patients exposed to trichloroethylene drink alcohol.

Adapted from Ciraulo D, Shader RI, Greenblatt DJ, Creelman WL. Drug Interactions in Psychiatry. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006, with permission.

Principles for the optimal treatment of patients with a dual diagnosis include the following: (a) flexibility (e.g., although the goal of treatment may be abstinence, for some patents, movement in the right direction is just as important to keep the person engaged in treatment); (b) repetition (e.g., a constant refocusing of attention for avoiding alcohol and for confronting their psychiatric symptoms is a priority); and (c) counseling (e.g., matching patients to the appropriate intervention). These factors are all fundamental to long-lasting treatment success. Medications, when appropriate (e.g., early and vigorous drug intervention with nonaddictive medications), may also help the patient stay in treatment; however, every effort must be made to use medications that do not induce euphoria or cause dependence, and are effective and safe even during relapse.[2,3]

Patients with both drug use and psychiatric disorders constitute a substantial and challenging subpopulation. Treating the alcohol use disorder alone predicts a poorer outcome for other disorders including early relapse. Early and aggressive treatment for each condition should be implemented. Furthermore, care must be taken to ensure that the medications prescribed are safe if combined with alcohol.[3]

ACKNOWLEDGMENT

The author acknowledges the authors for their contributions to the following chapters in previous versions of the textbook: Wendy O. Zizzo and Paolo V. Zizzo for their chapter on Drug Abuse and George A. Kenna for his chapter on Alcohol Use Disorders.

Tobacco Use and Dependence

Andrea S. Franks and Sarah E. McBane

	CORE PRINCIPLES	CHAPTER CASES
1	Cigarette smoking is the single most preventable cause of premature death in the United States. Smoking harms nearly every organ of the body, causing many diseases (including, but not limited to, cardiovascular disease, pulmonary disease, and cancers) and reducing the health of smokers in general. Quitting smoking has immediate as well as long-term benefits, reducing risks for diseases caused by smoking and improving health in general.	**Case 91-2 (Questions 1, 4),** **Case 91-3 (Question 1),** **Case 91-5 (Question 1),** **Case 91-6 (Question 1)**
2	Tobacco products are effective delivery systems for the drug nicotine. Nicotine is a highly addictive drug that activates the dopamine reward pathway in the brain that reinforces continued tobacco use. Nicotine withdrawal symptoms (e.g., irritability, anxiety, difficulty concentrating, restlessness, depressed mood, insomnia, impaired performance, increased appetite or weight gain, cravings) generally occur when nicotine is discontinued.	**Case 91-1 (Questions 2, 4),** **Case 91-3 (Question 1),** **Case 91-6 (Questions 1, 2)**
3	Constituents in tobacco smoke are associated with a number of clinically significant drug interactions.	**Case 91-4 (Questions 1, 3),** **Case 91-6 (Question 3)**
4	Tobacco dependence, a chronic disease that often requires repeated intervention and multiple attempts to quit, is characterized by physiologic dependence (addiction to nicotine) and behavioral habit of using tobacco.	**Case 91-1 (Question 5),** **Case 91-2 (Question 3),** **Case 91-3 (Question 1)**
5	Numerous effective medications, as delineated in the Clinical Practice Guideline, are available for treating tobacco use and dependence. Most patients should be encouraged to use one or more first-line agents, which include the nicotine patch, nicotine gum, nicotine lozenge, nicotine nasal spray, nicotine oral inhaler, sustained-release bupropion, and varenicline. All first-line agents approximately double quit rates, and therefore, the choice of therapy is based largely on contraindications, precautions, patient preference, and tolerability. In some cases, medications can be combined or used for extended durations. Although alternative therapies are available, these are not recommended because of insufficient evidence of efficacy.	**Case 91-1 (Questions 1–3),** **Case 91-2 (Questions 3, 4),** **Case 91-3 (Question 1),** **Case 91-4 (Question 2),** **Case 91-6 (Questions 1, 4)**
6	Comprehensive counseling, as defined by the Clinical Practice Guideline, includes asking about tobacco use, advising patients to quit, assessing readiness to quit, assisting patients with quitting, and arranging follow-	**Case 91-1 (Questions 2, 5),** **Case 91-3 (Question 1),** **Case 91-5 (Question 1),**

	up. This approach is referred to as “The 5 A’s.” Counseling and support can be provided a variety of ways, such as through individual counseling, group programs, telephone, or the Internet. Two components of counseling are especially effective and should be applied when assisting patients with quitting: practical counseling (problem solving or skills training) and social support delivered as part of treatment. Relapse is common, and clinicians should work with patients throughout the quit attempt to increase the chances for long-term abstinence.	**Case 91-6 (Questions 1, 2, 4)**
⑦	Brief tobacco dependence treatment (<3 minutes) is effective. In the absence of time or expertise, ask about tobacco use, advise patients to quit, and refer patients to other resources (e.g., telephone quitlines, web-based support, local programs) for additional assistance. This approach is referred to as “Ask-Advise-Refer.”	**Case 91-5 (Question 1)**

⑧	Patients with psychiatric disorders exhibit a higher prevalence of tobacco use and a disproportionately high level of tobacco-related morbidity and mortality.	**Case 91-6 (Question 1)**
⑨	Cigarettes are the most common form of tobacco used in the United States; however, other forms of tobacco exist (spit tobacco, pipes, cigars, bidis, hookah). All forms of tobacco are harmful.	**Case 91-2 (Question 2), Narrated PowerPoint slides on Forms of Tobacco**

Tobacco is a detrimental substance, and its use dramatically increases a person’s odds of dependence, disease, disability, and death. Cigarettes are the only marketed consumable product that when used as intended will contribute to the death of half or more of its users.[1] Tobacco products are carefully engineered formulations that optimize the delivery of nicotine, a chemical that meets the criteria for an addictive substance: (a) nicotine induces psychoactive effects, (b) it is used in a highly controlled or compulsive manner, and (c) behavioral patterns of tobacco use are reinforced by the pharmacologic effects of nicotine.[2] As a major risk factor for a wide range of diseases, including cardiovascular conditions, cancers, and pulmonary disorders, tobacco is the primary known preventable cause of premature death and disease in our society.[3] Since the Surgeon General’s first report on smoking in 1964, over 20 million American deaths have been attributed to smoking or secondhand smoke exposure.[3] Globally, almost 7 million people die annually from smoking (6 million) or being exposed to secondhand smoke (890,000).[4]

In the United States, smoking is responsible for more than 480,000 premature deaths each year.[3] In addition to the harm imposed on users of tobacco, exposure to secondhand smoke results in an estimated 50,000 deaths annually.[5,6] According to the Office of the US Surgeon General, there is no risk-free level of exposure to tobacco smoke.[2] Because of the health and societal burdens that it imposes, tobacco use and dependence should be addressed during each clinical encounter with all tobacco users.[7]

EPIDEMIOLOGY OF TOBACCO USE AND DEPENDENCE

In the United States, cigarettes are the most common form of tobacco that is consumed, but other forms are also prevalent: smokeless tobacco (chewing tobacco, oral snuff), pipes, cigars, clove cigarettes, bidis, and hookah. Electronic cigarettes (e-cigarettes) are growing in popularity. Electronic cigarettes, electronic nicotine delivery systems (ENDS), contain a liquid consisting of nicotine and other substances that is heated by an atomizer and inhaled as a vapor. Among adults, smoking prevalence varies by sociodemographic factors, including sex, race or ethnicity, education level, age, and poverty level. The Centers for Disease Control and Prevention (CDC) reported that in 2014, 21.3% of adults in the United States used a tobacco product every day or some days, with 17% reporting cigarette use.[8] Smoking prevalence is increased among persons with mental illness, with over one-third smoking cigarettes.[9]

Factors Contributing to Tobacco Use

Tobacco addiction is maintained by nicotine dependence.[10,11] Nicotine induces a variety of pharmacologic effects that lead to dependence.[12] However, tobacco dependence is not simply a matter of nicotine pharmacology—it is a result of the interplay of complex processes, including the desire for the direct pharmacologic actions of nicotine, the relief of withdrawal, learned associations, and environmental cues (e.g., advertising, the smell of a cigarette, or observing others who are smoking).[11] Physiologic factors, such as preexisting medical conditions (e.g., psychiatric comorbidities[9,11] and one's genetic profile), also can predispose individuals to tobacco use.[12,13]

Nicotine, the addictive component of tobacco, is rapidly absorbed and passes through the blood–brain barrier, contributing to its addictive nature. After inhalation, nicotine reaches the brain within seconds.[10] As such, smokers experience nearly immediate onset of the positive effects of nicotine, including pleasure, relief of anxiety, improved task performance, improved memory, mood modulation, and skeletal muscle relaxation.[10] These effects, mediated by alterations in neurotransmitter levels, reinforce continued use of nicotine-containing products.[10,11]

Nicotine Pharmacology

Nicotine (Nicotiana tabacum) is one of the few natural alkaloids that exist in the liquid state. Nicotine is a clear, weak base with a pK_α of 8.0.[14] In acidic media, nicotine is ionized and poorly absorbed; conversely, in alkaline media, nicotine is nonionized and well absorbed. Under physiologic conditions (pH = 7.4), a large proportion of nicotine is nonionized and readily crosses cell membranes.[14] Given the relation between pH and absorption, the tobacco industry and pharmaceutical companies are able to titrate the pH of their tobacco products and nicotine replacement therapy (NRT) products to maximize the absorption potential of nicotine.[14–16]

Once absorbed, nicotine induces a variety of central nervous system, cardiovascular, and metabolic effects. Nicotine stimulates the release of several neurotransmitters, inducing a range of pharmacologic effects such as pleasure (dopamine), arousal (acetylcholine, norepinephrine), cognitive enhancement (acetylcholine), appetite suppression (dopamine, norepinephrine, serotonin), learning (glutamate), memory enhancement (glutamate), mood modulation (serotonin), and reduction of anxiety and tension (β-endorphin and γ-aminobutyric acid [GABA]).[17] The dopamine reward pathway, a network that elicits feelings of pleasure in response to certain stimuli, is central to drug-induced reward. The neurons of the ventral tegmental area contain the neurotransmitter dopamine, which is released in the nucleus accumbens and in the prefrontal cortex. Immediately after inhalation, a bolus of nicotine enters the brain, stimulating the release of dopamine, which induces nearly immediate feelings of pleasure, along with relief of the symptoms of nicotine withdrawal. This rapid dose response reinforces repeated administration of the drug and perpetuates the smoking behavior.[11,17]

Chronic administration of nicotine has been shown to increase the number of nicotine receptors in specific regions of the brain.[18] This may represent upregulation in response to nicotine-mediated desensitization of the receptors and could play a role in nicotine tolerance and dependence.[17,18] Chronic nicotine administration also leads to tolerance of its behavioral and cardiovascular effects during the course of the day; however, tobacco users regain sensitivity to the effects of nicotine after overnight abstinence from nicotine,[10,11] as shown in Figure 91-1.[19] After smoking the first cigarette of the day, the smoker experiences marked pharmacologic effects, particularly arousal. No other cigarette throughout the day produces the same degree of pleasure or arousal. For this reason, many smokers describe the first cigarette as the most important one of the day. Shortly after the initial cigarette, tolerance begins to develop. Accordingly, the threshold levels for both pleasure or arousal and abstinence rise progressively throughout the day because the smoker becomes tolerant to the effects of nicotine. With continued smoking, nicotine accumulates, leading to an even greater degree of tolerance. Later in the day, each individual cigarette produces only limited pleasure or arousal; instead, smoking primarily alleviates nicotine withdrawal symptoms. Lack of exposure to nicotine overnight results in resensitization of drug responses (i.e., loss of tolerance). Most dependent smokers tend to smoke a certain number of cigarettes/day and tend to consume sufficient nicotine/day to achieve the desired effects of cigarette smoking and minimize the symptoms of nicotine withdrawal.[11,19] Withdrawal symptoms, which include anger, anxiety, depression, difficulty concentrating, impatience, insomnia, and restlessness, typically manifest within a few days after quitting, peak within a week, and subside within 2 to 4 weeks.[20] Tobacco users become adept at titrating their nicotine levels throughout the day to avoid withdrawal symptoms, maintain pleasure and arousal, and modulate mood.

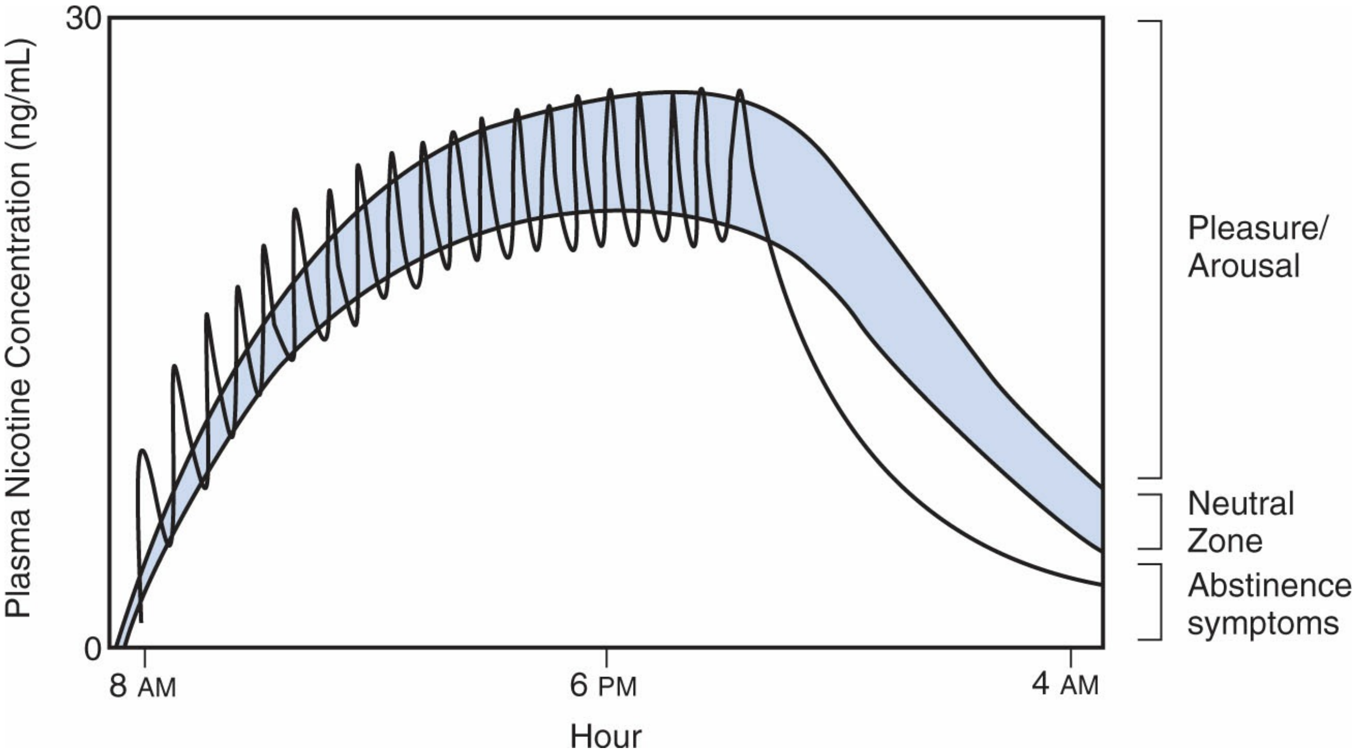

Figure 91-1 Nicotine addiction cycle throughout the day. The sawtooth line represents venous plasma concentrations of nicotine because a cigarette is smoked every 40 minutes between 8 AM and 9 PM. The upper solid line indicates the threshold concentration for nicotine to produce pleasure or arousal. The lower solid line indicates the concentrations at which symptoms of abstinence (i.e., withdrawal symptoms) from nicotine occur. The shaded area represents the zone of nicotine concentrations (neutral zone) in which the smoker is comfortable without experiencing either pleasure and arousal or abstinence symptoms. (Reprinted with permission from Benowitz NL. Cigarette smoking and nicotine addiction. Med Clin North Am. 1992;76(2):415.)

Nicotine is extensively metabolized in the liver and, to a lesser extent, in the kidney and lung. Approximately 70% to 80% of nicotine is metabolized to cotinine, an inactive metabolite.[14] The rapid metabolism of nicotine (half-life [$t_{1/2}$] = 2 hours) to inactive compounds underlies tobacco users' needs for frequent, repeated administration. The half-life of cotinine, however, is much longer ($t_{1/2}$ = 18–20 hours), and for this reason, cotinine is commonly used as a marker of tobacco use as well as a marker for exposure to secondhand smoke.[14] Measurement of cotinine cannot, however, differentiate between the nicotine from tobacco products and the nicotine from NRT products. Nicotine and other metabolites are excreted in the urine. Urinary excretion is pH dependent; the excretion rate is increased in acidic urine.[14] Nicotine crosses the placenta and accumulates in breast milk.[14]

Drug Interactions with Smoking

It is widely recognized that polycyclic aromatic hydrocarbons (PAHs) in tobacco smoke are responsible for most drug interactions with smoking.[21,22] PAHs, which result from incomplete combustion of tobacco, are potent inducers of several hepatic cytochrome-P450 microsomal enzymes (CYP1A1, CYP1A2, and possibly CYP2E1). Although other substances in tobacco smoke, including acetone, pyridines, benzene, nicotine, carbon monoxide, and heavy metals (e.g., cadmium), might also interact with hepatic enzymes, their effects appear to be less significant. Most drug interactions with tobacco smoke are pharmacokinetic, resulting from the induction of drug-metabolizing enzymes (especially CYP1A2) by compounds in tobacco smoke. Table 91-1 summarizes key interactions with smoking.[21,22,23] Patients who begin smoking, quit smoking, or dramatically alter their level of smoking might require dosage adjustments for some medications.

Health Consequences of Tobacco Use

All forms of tobacco are harmful, and there is no safe level of exposure to tobacco products. Smoking has a causal or contributory role in the development of a variety of medical conditions, affecting almost every organ in the body.[2,3]

SECONDHAND SMOKE EXPOSURE

Exposure to secondhand smoke, which includes the smoke from burning tobacco and that exhaled by the smoker, affects an estimated 88 million nonsmokers older than the age of 3 in the United States.[24] Secondhand smoke exposure causes disease and premature death in children and adults who do not smoke resulting in an estimated 50,000 deaths annually.[6] Millions of American children and adults are still exposed to secondhand smoke in their homes and workplaces despite substantial progress in tobacco control. Evidence indicates that there is no risk-free level of exposure to secondhand smoke. Only completely eliminating smoking in indoor spaces fully protects nonsmokers from exposure to secondhand smoke. Separating smokers from nonsmokers, cleaning the air, and ventilating buildings cannot eliminate exposure of nonsmokers to secondhand smoke.

Benefits of Quitting

Benefits of smoking cessation incurred soon after quitting (e.g., within 2 weeks–3 months) include improvements in pulmonary function, circulation, and ambulation. Smoking cessation results in measurable improvements in lung function (see Chapter 19, Chronic Obstructive Pulmonary Disease). One year after cessation, the excess risk of coronary heart disease is reduced to half that of continuing smokers. After 5 to 15 years, the risk of stroke is reduced to a rate similar to that of people who are lifetime nonsmokers, and 10 years after quitting, the chance of dying of lung cancer is approximately half that of continuing smokers. In addition, the risk of developing mouth, throat, esophagus, bladder, kidney, or pancreatic cancer is decreased. Finally, 15 years after quitting, the risk of coronary heart disease is reduced to a rate that is similar to that of people who have never smoked.[25] Similarly, more recent data suggest that smokers who quit for good over a sustained period have an overall mortality rate and death rate associated with cardiovascular disease, ischemic heart disease, and stroke that is similar to individuals who have never smoked. In contrast, individuals who had successfully quit, but later resumed smoking, had mortality risks that were significantly higher than lifetime nonsmokers.[26]

Table 91-1

Drug Interactions with Tobacco Smoke

Drug/Class	Mechanism of Interaction and Effects
Pharmacokinetic Interactions	
Alprazolam (Xanax)	■ Conflicting data on significance, but possible ↓ plasma concentrations (up to 50%) ↓ half-life (35%).
Bendamustine (Treanda)	■ **Metabolized by CYP1A2. Manufacturer recommends using with caution i smokers due to likely ↓ bendamustine concentrations, with ↑ concentrations of its two active metabolites.**
Caffeine	■ **↑ Metabolism (induction of CYP1A2); ↑ clearance (56%).** ■ **Caffeine levels likely increase after cessation.**
Chlorpromazine (Thorazine)	■ ↓ AUC (36%) and serum concentrations (24%). ■ ↓ Sedation and hypotension possible in smokers; smokers may require ↑ dosages.
Clopidogrel (Plavix)	■ **↑ Metabolism (induction of CYP1A2) of clopidogrel to its active metabolite.** ■ **Clopidogrel's effects are enhanced in smokers (≥10 cigarettes/day): significant ↑ platelet inhibition, ↓ platelet aggregation; although improved clinical outcomes have been shown, may also ↑ risk of bleeding.**

Clozapine (Clozaril)	■ **↑ Metabolism (induction of CYP1A2); ↓ plasma concentrations (18%).** ■ **↑ Levels on cessation may occur; closely monitor drug levels and reduce dose as required to avoid toxicity.**
Erlotinib (Tarceva)	■ **↑ Clearance (24%); ↓ trough serum concentrations (2-fold).**
Flecainide (Tambocor)	■ ↑ Clearance (61%); ↓ trough serum concentrations (25%). ■ Smokers may need ↑ dosages.
Fluvoxamine (Luvox)	■ **↑ Metabolism (induction of CYP1A2); ↑ clearance (24%); ↓ AUC (31%); Cmax (32%) and Css (by 39%).** ■ **Dosage modifications not routinely recommended but smokers may need ↑ dosages.**
Haloperidol (Haldol)	■ **↑ Clearance (44%); ↓ serum concentrations (70%); data are inconsistent therefore clinical significance is unclear.**
Heparin	■ Mechanism unknown but ↑ clearance and ↓ half-life are observed. Smoking has prothrombotic effects. ■ Smokers may need ↑ dosages because of PK and PD interactions.
Insulin, subcutaneous	■ Possible ↓ insulin absorption secondary to peripheral vasoconstriction; smoking may cause release of endogenous substances that cause insulin resistance. ■ PK and PD interactions likely not clinically significant but smokers may need ↑ dosages.
Irinotecan (Camptosar)	■ **↑ Clearance (18%); ↓ serum concentrations of active metabolite SN-38 (~40%; via induction of glucuronidation); ↓ systemic exposure resulting in lower hematologic toxicity and may reduce efficacy.** ■ **Smokers may need ↑ dosages.**
Methadone	■ Possible increase ↑ metabolism (induction of CYP1A2, a minor pathway for methadone.)- Carefully monitor response upon cessation.
Mexiletine (Mexitil)	■ ↑ Clearance (25%; via oxidation and glucuronidation); ↓ half-life (36%).
Olanzapine (Zyprexa)	■ **↑ Metabolism (induction of CYP1A2): ↑ clearance (98%); ↓ serum concentrations (12%).** ■ **Dosage modifications not routinely recommended but smokers may need ↑ dosages.**
Propranolol (Inderal)	■ ↑ Clearance (77%; via side-chain oxidation and glucuronidation).
Riociguat (Adempas)	■ **↓ Plasma concentrations (by 50%–60%)** ■ **Smokers may require dosages higher than 2.5 mg 3 times daily; consider dose reduction upon cessation.**
Ropinirole (Requip)	■ **↓ C_{max} (30%) and AUC (38%) in study with patients with restless legs syndrome.** ■ **Smokers may need ↑ dosages.**
Tacrine (Cognex)	■ Increase ↑ metabolism (induction of CYP1A2); decrease ↓ half-life (50%); seru concentrations 3-fold lower. -Smokers may need increased ↑ dosages.
Tasimelteon (Hetlioz)	■ Increased ↑ Metabolism (induction of CYP1A2); drug exposure decreased ↓ by 40%. -Smokers may need increased ↑ dosages.
Theophylline (Theo-Dur, etc.)	■ **↑ Metabolism (induction of CYP1A2); ↑ clearance (58%–100%); ↓ half-lif (63%).**

	Levels should be monitored if smoking is initiated, discontinued, or changed. **↑ Clearance with secondhand smoke exposure.** **Maintenance doses are considerably higher in smokers; ↑ Clearance also with secondhand smoke exposure.**
Tizanidine (Zanaflex)	↓ AUC (30%–40%) and ↓ half-life (10%) observed in male smokers.

Tricyclic antidepressants (e.g., imipramine, nortriptyline)	Possible interaction with tricyclic antidepressants in the direction of ↓ blood levels but the clinical significance is not established.
Warfarin	↑ Metabolism (induction of CYP1A2) of R-enantiomer; however, S-enantiomer is more potent and effect on INR is inconclusive. Consider monitoring INR on smoking cessation.
Pharmacodynamic Interactions	
Benzodiazepines (diazepam, chlordiazepoxide)	↓ Sedation and drowsiness, possibly caused by nicotine stimulation of central nervous system.
β-Blockers	Less effective antihypertensive and heart rate control effects; possibly caused by nicotine-mediated sympathetic activation. Smokers may need ↑ dosages.
Corticosteroids, inhaled	**Smokers with asthma may have less of a response to inhaled corticosteroids.**
Hormonal contraceptives (combined)	**↑ Risk of cardiovascular adverse effects (e.g., stroke, myocardial infarction, thromboembolism) in women who smoke and use combined hormonal contraceptives.** **↑ Risk with age and with heavy smoking (15 or more cigarettes/day) and i quite marked in women aged 35 and older.**
Serotonin 5-HT1 receptor agonists (triptans)	This class of drugs may cause coronary vasospasm; caution for use in smokers due to possible unrecognized CAD.

Bold rows indicate the most clinically significant interactions.

AUC, area under the curve; C_{max}, maximal concentration; Css, steady state concentration; INR, international normalized ratio; PD, pharmacodynamics; PK, pharmacokinetics.

Quitting at ages 30, 40, 50, and 60 results in 10, 9, 6, and 3 years of life gained, respectively.[1] On average, cigarette smokers die approximately 10 years younger than do nonsmokers, and of those who continue smoking, at least half will eventually die as a result of a tobacco-related disease. Persons who quit before age 35 add 10 years of life and have a life expectancy similar to men who had never smoked.[1] A reduction in smoking does not equate to a reduction in harm,[27] and even low levels of smoking (e.g., 1–4 cigarettes/day) have documented risks.[28,29] Therefore, decreasing the number of cigarettes smoked/day should be viewed as a positive step toward quitting, but should not be recommended as a targeted end point. For any patient who uses tobacco, the goal is complete, long-term abstinence from all nicotine-containing products.

Tobacco Use and Dependence: Treatment Approaches

Most tobacco users attempt to quit without assistance, despite the fact that persons who receive assistance are more likely to be successful in quitting.[7,30] Given the complexity of the tobacco dependence syndrome and the constellation of factors that contribute to tobacco use, treatment requires a multifaceted approach. To assist clinicians and other specialists in providing cessation treatment to patients who use tobacco, the US Public Health Service published the Clinical Practice Guideline for Treating Tobacco Use and Dependence. This document, which represents a distillation of more than 8,700 published articles,[7] specifies that clinicians can have an important impact on their patients' ability to quit. A meta-analysis of 29 studies[7] estimated that compared with patients who do not receive an intervention from a clinician, patients who receive a tobacco-cessation intervention from a physician clinician or a nonphysician clinician are 2.2 and 1.7 times, respectively, more likely to quit (at 5 or more months after cessation). Although even brief advice from a clinician has been shown to lead to increased odds of quitting,[7] more intensive counseling yields more dramatic increases in quit rates.[7] Other effective methods for delivery of counseling include group programs[7,31] and telephone counseling.[32] Internet-based interventions have become more prevalent in recent years, but a meta-analysis of 28 trials revealed inconsistent results.[33]

Numerous effective medications are available for tobacco dependence, and clinicians should encourage their use by all patients attempting to quit smoking—except when medically contraindicated or with specific populations for which there is insufficient evidence of effectiveness (i.e., pregnant women, smokeless tobacco users, light smokers, adolescents).[7] Although both pharmacotherapy and behavioral counseling are effective independently, patients' odds of quitting are substantially increased when the two approaches are used simultaneously.[34] Clinicians can have a significant impact on a patient's likelihood of success by recommending pharmacotherapy agents and by supplementing medication use with behavioral counseling as described later in this chapter.

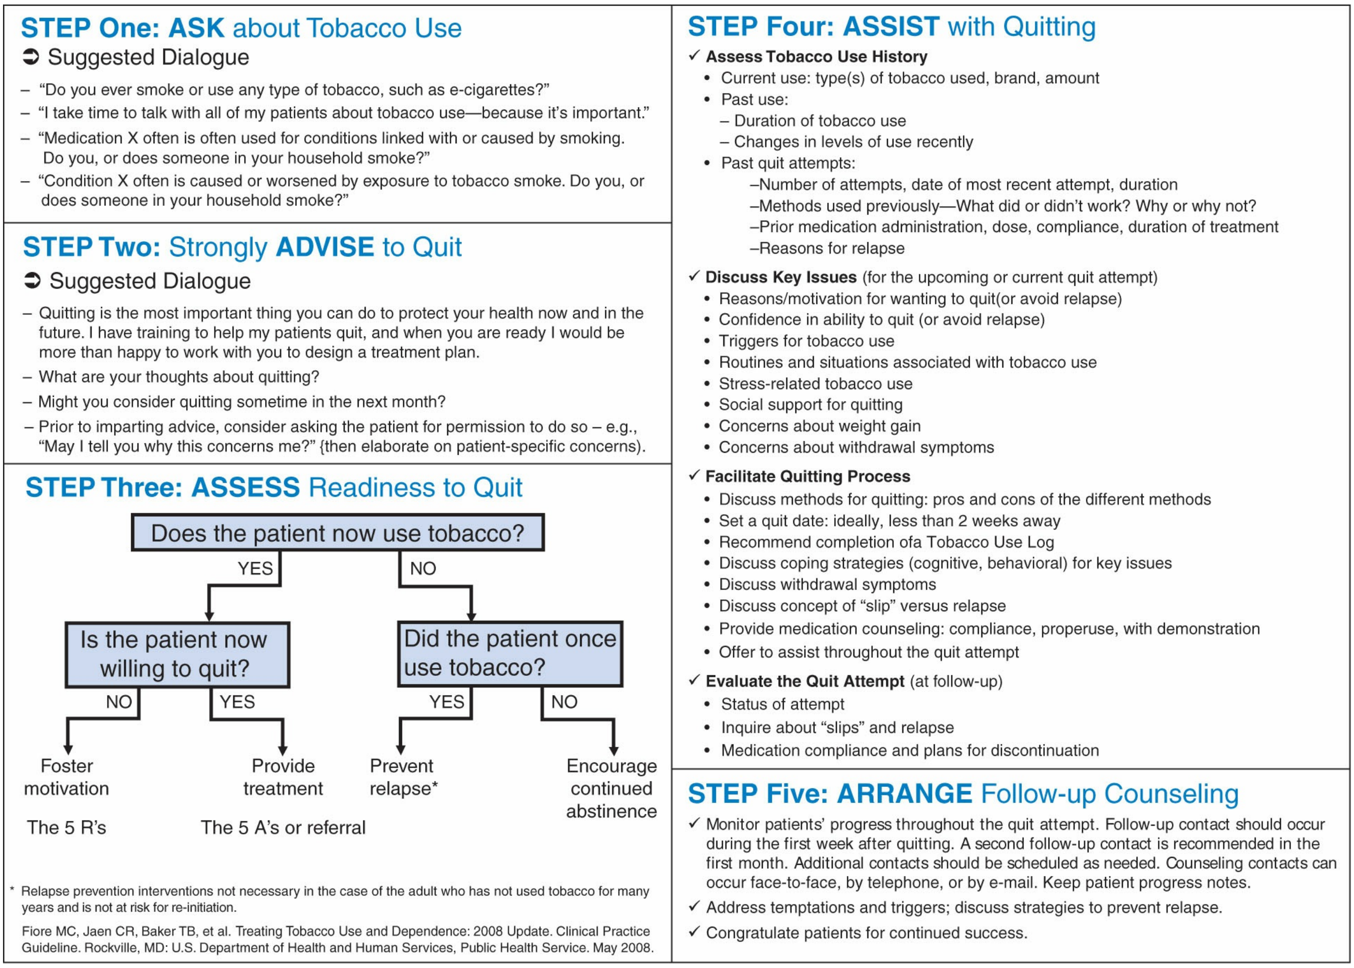
Assisting Patients with Quitting

BEHAVIORAL COUNSELING STRATEGIES

According to the Clinical Practice Guideline,[7] five key components constitute comprehensive counseling for tobacco cessation: (a) asking patients whether they use tobacco, (b) advising tobacco users to quit, (c) assessing patients' readiness to quit, (d) assisting patients with quitting, and (e) arranging follow-up care. These steps are referred to as the "5 A's" and are described, in brief, as follows. Figure 91-2 can be used as a guide for structuring counseling interactions.

- **Ask:** Screening for tobacco use is essential and should be a routine component of clinical care. The following question can be used to identify tobacco users: "Do you ever smoke or use any type of tobacco?" At a minimum, tobacco use status (current, former, never user) and level of use (e.g., number of cigarettes smoked/day) should be assessed and documented in the medical record. Also, patients should be asked about exposure to secondhand smoke.
- **Advise:** Tobacco users should be advised to consider quitting; the advice should clear and compelling, yet delivered with sensitivity and a tone of voice that communicates concern and a willingness to assist with quitting. When possible, messages should be personalized by relating advice to factors such as a patient's health status, medication regimen, personal reasons for wanting to quit, or the impact of tobacco use on others. For example, "I'm concerned because you are on two different inhalers for your emphysema. Quitting smoking is the single most important treatment to improve your breathing. I strongly encourage you to quit. Would you be interested in having me help you with this?"
- **Assess:** Key to the provision of appropriate counseling interventions is the assessment of a patient's readiness to quit. Patients should be categorized as being (a) not ready to quit in the next month; (b) ready to quit in the next month; (c) a recent quitter, having quit in the past 6 months; or (d) a former user, having quit more than 6 months ago.[7,35] This classification defines the clinician's next step, which is to provide counseling that is tailored to the patient's level of readiness to quit. As an example for a current smoker: "Mr. Malkin, what are your thoughts about quitting, and would you consider quitting sometime in the next month?" The counseling interventions for patients who are ready to quit will be different from those for patients who are not considering quitting.
- **Assist:** When counseling tobacco users, it is important that clinicians and patients view quitting as a process that might take months or even years to achieve. The goal is to promote forward progress in the process of change, with the target end point being sustained abstinence from all nicotine-containing products.

When counseling patients who are not ready to quit, an important first step is to foster motivation. Some patients are not convinced that quitting is important, but most recognize the need to quit and are simply not ready to make the commitment to do so. Often, patients have tried to quit multiple times and failed, and thus are too discouraged to try again. The "5 R's" can be applied to enhance motivation to quit [7] (Table 91-2) by clinicians offering to work closely with the patient in designing a treatment plan. Although it might be useful to educate patients about the pharmacotherapy options, it is inappropriate to prescribe a treatment regimen for patients who are not ready to quit. For patients who are not ready to quit in the next 30 days, encourage them to seriously consider quitting and ask the following questions:



STEP One: ASK about Tobacco Use

➲ Suggested Dialogue

- "Do you ever smoke or use any type of tobacco, such as e-cigarettes?"
- "I take time to talk with all of my patients about tobacco use—because it's important."
- "Medication X often is often used for conditions linked with or caused by smoking. Do you, or does someone in your household smoke?"
- "Condition X often is caused or worsened by exposure to tobacco smoke. Do you, or does someone in your household smoke?"

STEP Two: Strongly ADVISE to Quit

➲ Suggested Dialogue

- Quitting is the most important thing you can do to protect your health now and in the future. I have training to help my patients quit, and when you are ready I would be more than happy to work with you to design a treatment plan.
- What are your thoughts about quitting?
- Might you consider quitting sometime in the next month?
- Prior to imparting advice, consider asking the patient for permission to do so – e.g., "May I tell you why this concerns me?" {then elaborate on patient-specific concerns}.

STEP Three: ASSESS Readiness to Quit

Does the patient now use tobacco?
YES
NO
Is the patient now willing to quit?
NO
YES
Did the patient once use tobacco?
YES
NO
Foster motivation
The 5 R's
Provide treatment
The 5 A's or referral
Prevent relapse*
Encourage continued abstinence

* Relapse prevention interventions not necessary in the case of the adult who has not used tobacco for many years and is not at risk for re-initiation.

Fiore MC, Jaen CR, Baker TB, et al. Treating Tobacco Use and Dependence: 2008 Update. Clinical Practice Guideline. Rockville, MD: U.S. Department of Health and Human Services, Public Health Service. May 2008.

STEP Four: ASSIST with Quitting

✓ **Assess Tobacco Use History**
- Current use: type(s) of tobacco used, brand, amount
- Past use:
  - Duration of tobacco use
  - Changes in levels of use recently
- Past quit attempts:
  - Number of attempts, date of most recent attempt, duration
  - Methods used previously—What did or didn't work? Why or why not?
  - Prior medication administration, dose, compliance, duration of treatment
  - Reasons for relapse

✓ **Discuss Key Issues** (for the upcoming or current quit attempt)
- Reasons/motivation for wanting to quit(or avoid relapse)
- Confidence in ability to quit (or avoid relapse)
- Triggers for tobacco use
- Routines and situations associated with tobacco use
- Stress-related tobacco use
- Social support for quitting
- Concerns about weight gain
- Concerns about withdrawal symptoms

✓ **Facilitate Quitting Process**
- Discuss methods for quitting: pros and cons of the different methods
- Set a quit date: ideally, less than 2 weeks away
- Recommend completion ofa Tobacco Use Log
- Discuss coping strategies (cognitive, behavioral) for key issues
- Discuss withdrawal symptoms
- Discuss concept of "slip" versus relapse
- Provide medication counseling: compliance, properuse, with demonstration
- Offer to assist throughout the quit attempt

✓ **Evaluate the Quit Attempt** (at follow-up)
- Status of attempt
- Inquire about "slips" and relapse
- Medication compliance and plans for discontinuation

STEP Five: ARRANGE Follow-up Counseling

✓ Monitor patients' progress throughout the quit attempt. Follow-up contact should occur during the first week after quitting. A second follow-up contact is recommended in the first month. Additional contacts should be scheduled as needed. Counseling contacts can occur face-to-face, by telephone, or by e-mail. Keep patient progress notes.

✓ Address temptations and triggers; discuss strategies to prevent relapse.

✓ Congratulate patients for continued success.

Table 91-2

Enhancing Motivation to Quit: The "5 R's" for Tobacco-Cessation Counseling

- **Relevance**—Encourage patients to think about the reasons why quitting is important. Counseling should be framed such that it relates to the patient's risk for disease or exacerbation of disease, family or social situations (e.g., having children with asthma), health concerns, age, or other patient factors, such as prior experience with quitting.
- **Risks**—Ask patients to identify potential negative health consequences of smoking, such as acute risks (shortness of breath, asthma exacerbations, harm to pregnancy, infertility), long-term risks (cancer, cardiac, and pulmonary disease), and environmental risks (promoting smoking among children by being a negative role

model; effects of secondhand smoke on others, including children and pets).

- **Rewards**—Ask patients to identify potential benefits that they anticipate from quitting, such as improved health, enhanced physical performance, enhanced taste and smell, reduced expenditures for tobacco, less time wasted or work missed, reduced health risks to others (fetus, children, housemates), and reduced aging of the skin.
- **Roadblocks**—Help patients identify barriers to quitting and assist in developing coping strategies (Table 91-4) for addressing each barrier. Common barriers include nicotine withdrawal symptoms, fear of failure, a need for social support while quitting, depression, weight gain, and a sense of deprivation or loss.
- **Repetition**—Continue to work with patients who are successful in their quit attempt. Discuss circumstances i which smoking occurred to identify the trigger(s) for relapse; this is part of the learning process and will be useful information for the next quit attempt. Repeat interventions when possible.

Reprinted from Fiore MC et al. Treating Tobacco Use and Dependence: 2008 Update. Clinical Practice Guideline. Rockville, MD: Public Health Service, U.S. Department of Health and Human Services; 2008.

1. Do you ever plan to quit?
   If the patient responds "no," the clinician should ask, "What would have to change for you to decide to quit?" If the patient responds "nothing," then offer to assist, if or when the patient changes his or her mind. If the patient responds "yes," the clinician should continue with question 2.
2. What might be some benefits of quitting now, instead of later?
   The longer a patient smokes, quitting generally becomes more difficult. Most patients will agree that there is never an ideal time to quit, and procrastinating a quit date has more negative effects than positive.
3. What would have to change for you to decide to quit sooner?
   This question probes patients' perceptions of quitting, which reveals some of the barriers to quitting that can then be discussed.

For patients who are ready to quit (i.e., in the next month), the goal is to work with the patient in designing an individualized treatment plan, addressing the key issues listed under the "Assist" component of Figure 91-2.[23] The first steps are to discuss the patient's tobacco use history, inquiring about levels of smoking, number of years smoked, methods used previously for quitting (what worked, what did not work and why), and reason(s) for previous failed quit attempts. Clinicians should elicit patients' opinions about the different medications for quitting and should work with patients in selecting the quitting methods (e.g., medications, behavioral counseling programs). Although it is important to recognize that pharmaceutical agents might not be appropriate, desirable, or affordable for all patients, clinicians should educate patients that medications, when taken correctly, can substantially increase the likelihood of success.

Patients should select a quit date, ideally within the next 2 weeks. This allows sufficient time to prepare for the quit attempt, including mental preparation, preparation of the environment, removing all tobacco products and ashtrays from the home, car, and workspace, and soliciting support their family, friends, and coworkers. Additional strategies for coping with quitting are shown in Table 91-3. Patients should be counseled about withdrawal symptoms, medication use, and the importance of receiving behavioral counseling throughout the quit attempt. Finally, patients should be commended for taking important steps toward improving their health.

- **Arrange:** Because patients' ability to quit increases when multiple counseling interactions are provided, arranging follow-up counseling is an important element of treatment for tobacco dependence. Follow-up contact should occur soon after the quit date, preferably during the first week. A second follow-up contact is recommended within the first month after quitting.[7] Additional follow-up contacts should occur to monitor patient progress, assess compliance with pharmacotherapy regimens, and provide additional support.

Relapse prevention counseling should be part of every follow-up contact with patients who have recently quit smoking. When counseling recent quitters, it is important to address challenges in countering withdrawal symptoms and cravings or temptations to use tobacco. A list of strategies for key triggers or temptations for tobacco use is provided in Table 91-3.[23] Importantly, because tobacco use is a habitual behavior, patients should be advised to alter their daily routines; this helps disassociate specific behaviors from the use of tobacco. Patients who slip and smoke a cigarette (or use any form of tobacco) or experience a full relapse back to habitual tobacco use should be encouraged to think through the scenario in which tobacco use first occurred and identify the trigger(s) for relapse. This process provides valuable information for future quit attempts.

PHARMACOTHERAPY OPTIONS

All smokers who are trying to quit should be encouraged to use one or more US Food and Drug Administration (FDA)-approved pharmacologic aids for cessation. Potential exceptions that require special consideration include medical contraindications or use in specific populations for which there is insufficient evidence of effectiveness (i.e., pregnant women, smokeless tobacco users, light smokers, adolescents).[7] Pharmacotherapy should always be combined with behavioral support and counseling. Currently, the FDA-approved first-line agents that have been shown to be effective in promoting smoking cessation include five NRT dosage forms, sustained-release bupropion, and varenicline.[7] The choice of therapy is dictated by considerations such as patient preference for a given agent, previous experience with cessation medications, current medical conditions, previous levels of smoking, medication adherence issues, and the patient's out-of-pocket costs. Dosing information, precautions, and adverse effects for the first-line agents are shown in Table 91-4.

Table 91-3

Cognitive and Behavioral Strategies for Tobacco Cessation

Cognitive Strategies	
Focus on retraining the way a patient thinks. Often, patients will deliberate on the fact that they are thinking about a cigarette, and this leads to relapse. Patients must recognize that thinking about a cigarette does not mean they need to have one.	
Review commitment to quit	Each morning, say, "I am proud that I made it through another day without tobacco!" Remind oneself that cravings and temptations are temporary and will pass. Announce, either silently or aloud, "I am a nonsmoker, and the temptation will pass."
Distractive thinking	Deliberate, immediate refocusing of thinking toward other thoughts when cued by thoughts about tobacco use.
Positive self-talks, "pep talks"	Say "I can do this" and remind oneself of previous difficult situations in which tobacco use was avoided.
Relaxation through imagery	Center mind toward positive, relaxing thoughts.
Mental rehearsal, visualization	Preparing for situations that might arise by envisioning how best to handle them. For example, envision what would happen if offered a cigarette by a friend—mentally craft and rehearse a response, and perhaps even practice it by saying it aloud.
Behavioral Strategies	
Involve specific actions to reduce risk for relapse. These strategies should be considered prior to quitting, after determining patient-specific triggers and routines or situations associated with tobacco use. Below are strategies for several of the common cues or causes for relapse.	
Stress	Anticipate upcoming challenges at work, at school, or in personal life. Develop a substitute plan for tobacco use during times of stress (e.g., use deep breathing, take a break or leave the situation, call a supportive friend or family member, or use nicotine replacement therapy to manage situational cravings).
Alcohol	Drinking alcohol can lead to relapse. Consider limiting or abstaining from alcohol during the early stages of quitting.
Other tobacco users	Quitting is more difficult when around other tobacco users. This is especially difficult if there is another tobacco user in the household. During the early stages of quitting, limit prolonged contact with individuals who are using tobacco. Ask coworkers, friends, and housemates not to smoke or use tobacco in your presence.
Oral gratification needs	Have nontobacco oral substitutes (e.g., gum, sugarless candy, straws, toothpicks, lip balm, toothbrush, nicotine replacement therapy, bottled water) readily available.
Automatic smoking routines	Anticipate routines that are associated with tobacco use and develop an alternative plan.
	Examples:
	Morning coffee: change morning routine, drink tea instead of coffee, take shower before drinking coffee, take a brisk walk shortly after awakening.
	While driving: remove all tobacco from car, have car interior detailed, listen to an audio book or talk radio, use oral substitutes.
	While on the phone: stand while talking, limit call duration, change phone location, keep hands occupied by doodling or sketching.
	After meals: get up and immediately do dishes or take a brisk walk after eating, call supportive friend.

Postcessation weight gain	Do not attempt to modify multiple behaviors at one time. If weight gain is a barrier to quitting, engage in regular physical activity and adhere to a healthful diet (as opposed to strict dieting). Carefully plan and prepare meals, increase fruit and water intake to create a feeling of fullness, and chew sugarless gum or eat sugarless candies. Consider use of pharmacotherapy shown to delay weight gain (e.g., nicotine gum, lozenge, or sustained-release bupropion).
Cravings for tobacco	Cravings for tobacco are temporary and usually pass within 5–10 minutes. Handle cravings through distractive thinking, take a break, do something else, take deep breaths.

FIRST-LINE AGENTS

Nicotine Replacement Therapy

NRT improves cessation rates by reducing the physical withdrawal symptoms associated with tobacco cessation whereas the patient focuses on behavior modification and coping with the psychological aspects of quitting. In addition, because the onset of action for NRT is not as rapid as that of nicotine obtained through smoking, patients become less accustomed to the nearly immediate, reinforcing effects of inhaled nicotine. A meta-analysis found that all NRT formulations result in statistically significant improvements in abstinence rates when compared with placebo. Patients using NRT are 1.6 times as likely to quit smoking than are those receiving placebo.[36] Figure 91-3 depicts the concentration–time curves for the various NRT formulations, compared with a cigarette and snuff, a smokeless form of tobacco.[37–39] Nicotine nasal spray reaches its peak concentration most rapidly. The nicotine gum, lozenge, and oral inhaler have similar concentration curves, and the nicotine transdermal patch has the slowest onset, but offers more consistent blood levels of nicotine for a sustained period. Although ideally tobacco use stops when NRT is initiated, some patients may continue to occasionally use tobacco products after beginning NRT. This allows patients more flexibility with continuing to use NRT if they slip and use tobacco products, or with initiating NRT in an effort to decrease the number of cigarettes smoked prior to complete cessation. (the "reduce to quit" method)[34,40,41] Initiating nicotine patch prior to a quit attempt may be more effective than applying the patch on the quit date. However, data are conflicting, and the evidence does not support using other forms of NRT prior to the quit date.[41]

Sustained-release Bupropion

Sustained-release bupropion is an atypical antidepressant medication hypothesized to promote smoking cessation by blocking the reuptake of dopamine and norepinephrine in the central nervous system[7] and possibly by acting as a nicotine receptor antagonist.[42] These neurochemical effects are believed to modulate the dopamine reward pathway and reduce cravings for nicotine and symptoms of withdrawal.[7] Use of sustained-release bupropion approximately doubles the long-term abstinence rate when compared with placebo.[7,43]

Varenicline

Varenicline is a partial agonist that binds with high affinity and selectivity at $\alpha_4\beta_2$ neuronal nicotinic acetylcholine receptors.[44] The efficacy of varenicline in smoking cessation is believed to be the result of sustained, low-level agonist activity at the receptor site combined with competitive inhibition of nicotine binding. The partial agonist activity induces modest receptor stimulation, leading to increased dopamine levels, which attenuates the symptoms of nicotine withdrawal. In addition, by blocking the ability of nicotine to activate $\alpha_4\beta_2$ nicotinic acetylcholine receptors, varenicline inhibits the surges of dopamine release that are believed to be responsible for the reinforcement and reward associated with smoking.[44,45] Use of varenicline more than doubles the chances of quitting when compared to placebo.[7,46] Patients should be monitored for neuropsychiatric symptoms, including changes in behavior, mood, or suicidal thoughts and behavior.[47]

SECOND-LINE AGENTS

Although not FDA-approved specifically for smoking cessation, the prescription medications clonidine and nortriptyline are recommended as second-line agents.[7] Lack of an FDA-approved indication for smoking cessation and less desirable side-effect profiles currently prohibit these agents from achieving first-line classification.[7]

PHARMACOTHERAPY FOR TREATING TOBACCO USE AND DEPENDENCE

Transdermal Nicotine Patch

CASE 91-1

QUESTION 1: T.B. is a 32-year-old woman who is enrolled in a worksite smoking-cessation program. During the previous group session, the cessation counselor discussed the various medications for cessation. T.B. has set her quit date for 1 week from today, and she is interested in starting the nicotine transdermal patch. She is currently smoking 1.5 packs/day (PPD), which is a reduction from the 2 PPD she had been smoking for the past 10 years. T.B. reports she smokes several cigarettes in succession immediately after waking in the morning. She takes no medications and has no medical problems. Which nicotine transdermal product should T.B. select, and how should it be used?

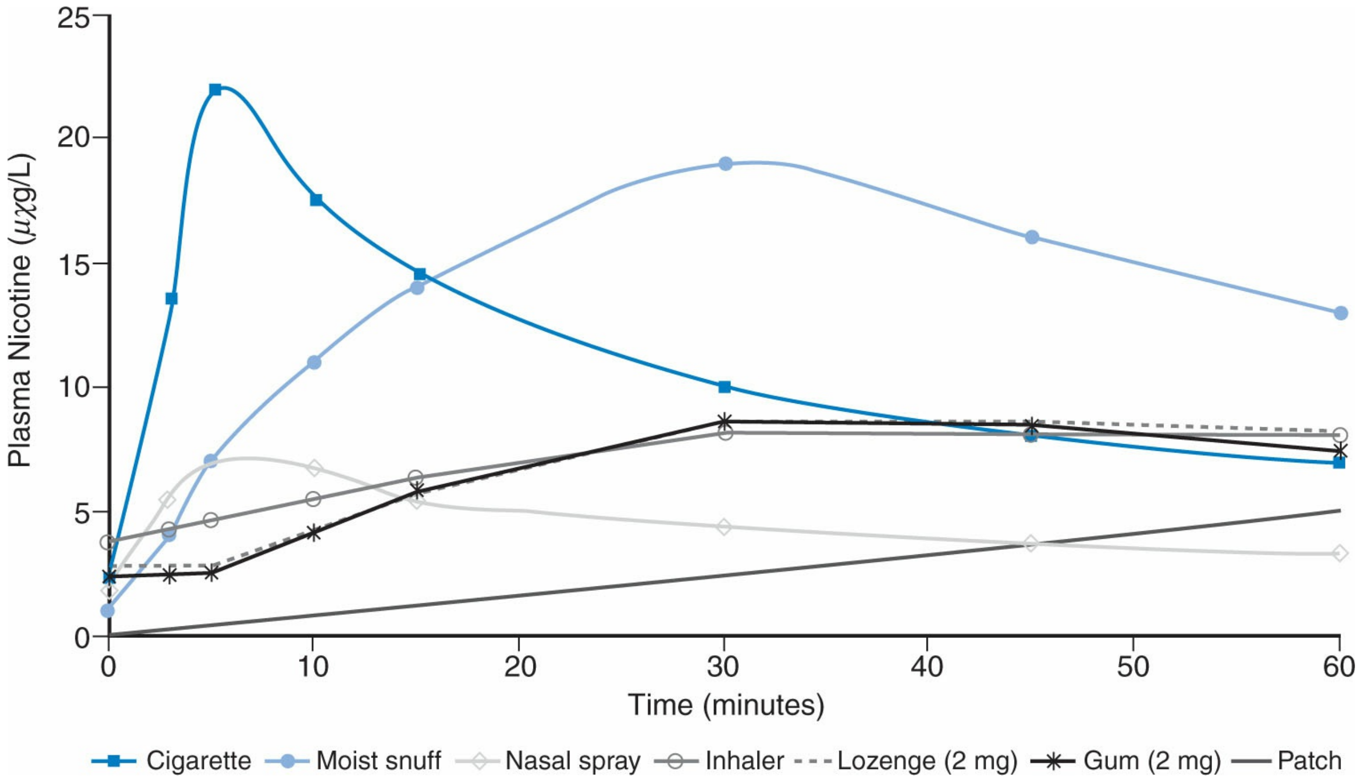

Figure 91-3 Plasma nicotine concentrations for various nicotine-containing products. (Reprinted with permission from Rx for Change: Clinician-Assisted Tobacco Cessation. Copyright © 1999–2017. The Regents of the University of California. All rights reserved. Plasma nicotine concentration curves derived from Choi JH et al. Pharmacokinetics of a nicotine polacrilex lozenge. Nicotine Tob Res. 2003;5(5):635; Schneider NG et al. The nicotine inhaler: clinical pharmacokinetics and comparison with other nicotine treatments. Clin Pharmacokinet. 2001;40(9):661; and Fant RV et al. Pharmacokinetics and pharmacodynamics of moist snuff in humans. Tob Control. 1999;8(4):387.)

Transdermal nicotine delivery systems consist of an impermeable surface layer, a nicotine reservoir, an adhesive layer, and a removable protective liner. Although the transdermal delivery technology varies by manufacturer, nicotine is well absorbed, with 68% to 82% of the dose released from 24-hour patch formulations systemically bioavailable across the skin. Plasma nicotine concentrations from the patch rise slowly during 1 to 4 hours and peak within 3 to 12 hours after application.[14] Levels of nicotine achieved with the transdermal patch are lower and fluctuate less than do those achieved with tobacco products or other NRT formulations (Fig. 91-3).

The transdermal nicotine patch exhibits significantly improved abstinence rates relative to placebo.[7,35] A meta-analysis of 25 randomized, controlled trials found treatment with the nicotine patch (6–14 weeks) approximately doubled the likelihood of long-term abstinence compared with placebo.[7]

DOSING

The manufacturers' recommended dosages are listed in Table 91-4. In general, higher levels of smoking necessitate the use of higher-strength formulations and a longer duration of therapy. Ultimately, the starting dose, rate of tapering, and total duration of therapy must be individualized to the patient's baseline smoking levels, development of side effects (e.g., nausea, dyspepsia, nervousness, dizziness, sweating), and the presence or absence of withdrawal symptoms. T.B. currently smokes 30 cigarettes/day, and thus she should initiate the regimen using the 21-mg/day patch.

PATIENT EDUCATION

T.B. should be instructed to apply the patch to a clean, dry, hairless area of skin on the upper body or the upper outer part of her arm at approximately the same time each day. To minimize the potential for local skin reactions, the patch application site should be rotated daily, and the same area should not be used again for at least 1 week. After patch application, T.B. should ensure that the patch adheres well to the skin, especially around the edges. The clinician should reassure T.B. that water will not reduce the effectiveness of the nicotine patch if it is applied correctly, and she may bathe, shower, swim, or exercise while wearing the patch. Finally, T.B. should be advised to discontinue use of the nicotine patch and contact a healthcare provider if skin redness caused by the patch does not resolve after 4 days; if the skin swells or a rash develops; if irregular heartbeat or palpitations occur; or if she experiences symptoms of nicotine overdose such as nausea, vomiting, dizziness, diarrhea, sweating, weakness, or rapid heartbeat.

ADVERSE REACTIONS

CASE 91-1, QUESTION 2: Ten days later, T.B. calls to complain of an itchy rash that she believes is caused by the nicotine patch. She noticed the rash yesterday when she removed the first patch from her left upper arm. This morning, after removing the second patch from her right upper arm, she noticed a similar rash. T.B. describes the skin on her right arm as slightly red but not swollen; the rash on her left arm has only a faint trace of pink discoloration. Her last cigarette was 2 days ago. How should T.B. be managed at this time?

The most common side effects associated with the nicotine patch are local reactions (erythema, burning, and pruritus) at the skin application site. These reactions are generally caused by skin occlusion or sensitivity to the patch adhesives. Rotating the patch application sites on a daily basis minimizes skin irritation;

nonetheless, skin reactions to the patch adhesives occur in up to 50% of patch users. Fewer than 5% of patients discontinue therapy because of a skin reaction.[7]

T.B. appears to be experiencing a mild skin reaction and should be reassured that it is common for the skin to appear erythematous for up to 24 to 48 hours after the patch is removed. T.B. can apply topical hydrocortisone cream (0.5% or 1%) or triamcinolone cream (0.5%), or she can take an oral antihistamine for symptomatic treatment.[7] Another option would be to try a different brand of patch as the adhesive may vary. Because the rash on her left arm has nearly resolved, it is reasonable for T.B. to continue using the nicotine transdermal patch provided that the erythema is not too bothersome.

Other less common side effects associated with the transdermal nicotine patch include vivid or abnormal dreams, insomnia, and headache. Sleep disturbances likely result from nocturnal nicotine absorption. Patients experiencing troublesome sleep disturbances should be instructed to remove the patch before bedtime and apply a new patch as soon as possible after waking the following morning.[7]

The clinician should also provide behavioral counseling support by asking T.B. about the current quit attempt. Appropriate issues to address include her confidence in remaining tobacco free, situations in which she has been tempted to smoke and potential triggers for relapse, nicotine withdrawal symptoms, her social support system for quitting, and any other questions or concerns she might have. It is reasonable to review potential coping strategies (behavioral and cognitive; Table 91-4) and schedule a future follow-up call. The clinician should commend T.B. for her decision to quit, congratulate her for remaining free of cigarettes for 48 hours, and reassure her that skin irritation is a common, yet generally manageable, complication with the nicotine patch.

PRODUCT SELECTION CONSIDERATIONS

The primary advantage of the transdermal nicotine patch compared with other NRT formulations is that the patch is easy to use, releases a continuous dose of nicotine throughout the day, and requires administration only once daily. Disadvantages of the patch include a high incidence of skin irritation associated with the patch adhesives and the inability to acutely adjust the dose of nicotine to alleviate symptoms of withdrawal. Finally, patients with underlying dermatologic conditions (e.g., psoriasis, eczema, atopic dermatitis) should not use the patch because they are more likely to experience skin irritation.[7]

CASE 91-1, QUESTION 3: T.B. would like to discontinue the nicotine transdermal patch. She would like to purchase a nonprescription smoking-cessation medication and wants to know whether the gum or lozenge is an effective alternative. What options would you recommend? What factors should be considered?

Nicotine Gum

Nicotine polacrilex gum is a resin complex of nicotine and polacrilin in a chewing gum base that provides slow release and absorption of nicotine across the oral mucosa. The product is available in 2- and 4-mg strengths, and in multiple flavors. The gum has a distinct, tobacco-like, slightly peppery, minty, or fruity taste and contains buffering agents to increase the salivary pH, which enhances the buccal absorption of nicotine. The amount of nicotine absorbed from each piece is variable, but when used properly, approximately 1.6 and 2.2 mg of nicotine is absorbed from each 2- and 4-mg piece of gum, respectively.[14] Peak plasma concentrations of nicotine are achieved approximately 30 minutes after chewing a single piece of gum and then slowly decline thereafter (Fig. 91-3). Patients using nicotine gum are significantly more likely to remain abstinent compared with those receiving placebo.[7,35]

DOSING

Table 91-4 outlines the manufacturers’ recommended dosing schedule for the nicotine gum. The recommended dosage of the nicotine gum is based on the “time to first cigarette” (TTFC) of the day. Having a strong desire or need to smoke soon after waking is viewed as a key indicator of nicotine dependence.[48] Therefore, patients who smoke their first cigarette of the day within 30 minutes of waking are likely to be more highly dependent on nicotine and require higher dosages than those who delay smoking for more than 30 minutes after waking (Table 91-4). The “chew and park” method (Table 91-4) allows for the slow, consistent release of nicotine. Patients can use additional pieces of gum (to the daily maximum of 24 pieces/day) if cravings occur between scheduled doses. In general, patients who smoke a greater number of cigarettes/day will require more nicotine gum to alleviate their cravings than will patients who smoke fewer cigarettes/day. It is preferable to use the gum on a fixed schedule of administration, tapering during 1 to 3 months rather than using it only as needed to control cravings.[7]

PATIENT EDUCATION

Proper chewing technique is crucial when using the nicotine gum, using the “chew and park” method (Table 91-4). The chew and park steps should be repeated until most of the nicotine is extracted; this generally occurs after 30 minutes and becomes obvious when chewing no longer elicits the characteristic taste or tingling sensation.

Patients should be warned that the absorption and therefore the effectiveness of nicotine gum might be reduced by acidic beverages (e.g., coffee, juices, wine, soft drinks),[49] which transiently reduce the salivary pH. To prevent this interaction, patients should be advised not to eat or drink (except water) for 15 minutes before or while using the nicotine gum.

ADVERSE REACTIONS

Most of the common side effects (Table 91-4) can be minimized or prevented by using proper chewing technique.[7] Patients should be warned that chewing the gum too rapidly may result in excessive release of nicotine, leading to lightheadedness, nausea, vomiting, irritation of the throat and mouth, hiccups, and indigestion.

PRODUCT SELECTION CONSIDERATIONS

Advantages of nicotine gum include the fact that this formulation may be used to satisfy oral cravings and the 4-mg strength might delay weight gain.[7] For these reasons, the gum may be particularly beneficial for patients who have weight-gain concerns or for patients who report boredom as a trigger for smoking. The gum might also be advantageous for patients who desire flexibility in dosing and prefer the ability to self-regulate nicotine levels to manage withdrawal symptoms. Some patients may find that the viscous consistency of the gum makes it difficult to use because it sticks to dental work. Others may find it difficult or socially unacceptable to chew the gum so frequently. Nicotine gum should not be used by patients with temporomandibular joint (TMJ) conditions.

Nicotine Lozenge

The nicotine polacrilex lozenge is a resin complex of nicotine and polacrilin in a sugar-free, flavored lozenge. The product is available in 2- and 4-mg strengths, which are meant to be consumed like hard candy or other medicinal lozenges (e.g., sucked and moved from side to side in the mouth until fully dissolved). A mini-lozenge is also available. Because the nicotine lozenge dissolves completely, it delivers approximately 25% more nicotine than does an equivalent dose of nicotine gum.[35] Like the nicotine gum, the lozenge also contains buffering agents (sodium carbonate and potassium bicarbonate) to increase salivary pH, thereby enhancing buccal absorption of the nicotine. Peak nicotine concentrations of nicotine with the lozenge are achieved after 30 to 60 minutes of use and then slowly decline thereafter (Fig. 91-3).The nicotine lozenge approximately doubles 6-month abstinence rates compared with placebo.[35]

DOSING

Table 91-4 outlines the manufacturers' recommended dosing schedule for the nicotine lozenge. Like the nicotine gum, the lozenge is dosed based on the TTFC. Patients are more likely to succeed if they use the lozenge on a fixed schedule rather than as needed. Patients can use additional lozenges (up to 5 lozenges in 6 hours or a maximum of 20 lozenges/day) if cravings occur between scheduled doses.

PATIENT EDUCATION

Similar to the gum, the nicotine lozenge is a specially formulated nicotine delivery system that must be used properly for optimal results. The lozenge should be allowed to dissolve slowly in the mouth; when nicotine is released, a warm, tingling sensation may be experienced. The patient should occasionally rotate the lozenge to different areas of the mouth to reduce the potential for mucosal irritation. When used correctly, the lozenge should completely dissolve within 30 minutes. Patients should be counseled not to chew or swallow the lozenge because this increases the incidence of gastrointestinal-related side effects.

As with the gum, patients should be cautioned that the effectiveness of the nicotine lozenge may be reduced by acidic beverages such as coffee, juices, wine, or soft drinks.[49] Patients should be advised not to eat or drink (except water) for 15 minutes before or while using the nicotine lozenge.

ADVERSE REACTIONS

In general, the nicotine lozenge is well tolerated. The most common side effects include nausea, hiccups, cough, dyspepsia, headache, and flatulence. Patients who use more than one lozenge at a time, continuously use one lozenge after another, or chew or swallow the lozenge are more likely to experience dyspepsia or hiccups.

PRODUCT SELECTION CONSIDERATIONS

The nicotine lozenge is similar to the nicotine gum formulation in that it may be used to satisfy oral cravings, the 4-mg strength might delay weight gain,[7,49] and patients can self-titrate therapy to acutely manage withdrawal symptoms. Because the lozenge does not require chewing, many patients find this to be a more discreet nicotine delivery system. The disadvantages of the lozenge are the fact that it requires frequent dosing, and the gastrointestinal side effects (nausea, hiccups, and heartburn) may be bothersome.

T.B. has expressed interest in either the nicotine gum or lozenge formulation for her quit attempt. Both agents are effective, and the choice of therapy is dependent on the patient’s perceptions and expectations regarding treatment, including the ability to comply with the regimen, previous experience with cessation medications, and other concerns (e.g., adverse effects, weight gain, cost of medications). T.B. would be a candidate for either agent provided she is able to comply with the frequent dosing schedule (one lozenge or piece of gum every 1–2 hours while she is awake). T.B. smokes her first cigarette of the day immediately after waking in the morning and she smokes approximately 30 cigarettes/day; this smoking pattern suggests a higher degree of nicotine dependence, and therefore T.B. would benefit from a higher dose of NRT. T.B. should initiate treatment with the 4-mg strength of either the nicotine lozenge or nicotine gum dosed every 1 to 2 hours while she is awake and tapered according to the schedule outlined in Table 91-4.

Postcessation Weight Gain

CASE 91-1, QUESTION 4: T.B. is very concerned about gaining weight after she quits smoking. Is weight gain common after quitting, and if so, how can this be prevented?

Most tobacco users gain weight after quitting, and clinicians should neither deny the likelihood of weight gain nor minimize its significance.[7] For nearly all patients, the health risks associated with postcessation weight gain are negligible compared with the risks of continued smoking.

Most quitters gain fewer than 10 lb, but there is a broad range of weight gain reported, with up to 10% of quitters gaining as much as 30 lb.[7] In general, women tend to gain more weight than men. In a study of nearly 6,000 smokers who were followed for 5 years after quitting, the average weight gain during the follow-up period was 19.2 and 16.7 lb among women and men, respectively.[50]

The weight-suppressing effects of tobacco are well known. However, the mechanisms to explain why most successful quitters gain weight are not completely understood. Smokers have been found to have an approximately 10% higher metabolic rate compared with nonsmokers.[51] Increased postcessation caloric intake might result from an increase in appetite, improved sense of taste, or a change in the hand-to-mouth ritual through the substitution of tobacco with food.

In general, a patient is less likely to be successful if he or she attempts to change multiple behaviors at once. For most patients, strict dieting to prevent weight gain, especially during the early stages of quitting, is generally not recommended.[7] T.B. should be counseled that the average weight gain of fewer than 10 lb is less detrimental to her overall health than is continued smoking. Although exercise interventions have not been shown to reduce weight gain among quitters,[52] it should not be ruled out as a recommendation for T.B. because she expresses significant concern about weight gain, and this might be a barrier to her quitting. Modest increases in activity can help with weight gain and exercise can serve as a behavioral substitution for tobacco use. Furthermore, T.B. should be advised to plan her meals in advance to avoid binge eating, increase her water intake to create a feeling of fullness, chew sugarless gum, and limit alcohol consumption. T.B. may consider pharmacotherapy options that have been shown to delay weight gain including NRT, varenicline, or sustained-release bupropion.[7,52] It is important to note, however, that none of the medications have been shown to prevent weight gain in the long term.[7,52]

Relapse Back to Smoking

CASE 91-1, QUESTION 5: During a follow-up contact, the clinician learns that T.B. smoked half a pack of cigarettes at a party over the weekend and has relapsed to her previous smoking levels after not having smoked for more than a month. How should the clinician respond?

The clinician should thank T.B. for being honest about her smoking and ask whether she is comfortable discussing the circumstances during which the smoking occurred. At the time of her smoking, where was she, who was she with, how did she get access to cigarettes, and how was she feeling at the time? What, specifically, were the triggers for her relapse (e.g., alcohol, depression, friends who were smoking around her)? It is important that the clinician help the patient to use this information as part of the learning process, but it also is important to focus on the "positive," such as T.B.'s ability to have remained tobacco free for more than 1 month. Four weeks after quitting, most physical effects of nicotine withdrawal have completely resolved, and thus, the relapse trigger for T.B. likely was psychological or situational and could be abated through application of effective coping techniques. After an informative discussion about the situation in which the smoking occurred, it is important that the clinician works with the patient in identifying strategies for avoiding relapse in the future (Table 91-3).

Smoking and Cardiovascular Disease

CASE 91-2

QUESTION 1: P.J. is a 62-year-old man admitted for an elective coronary artery bypass graft (CABG) procedure. His medical history is significant for angina, hypertension, dyslipidemia, peripheral vascular disease (PVD), and allergic rhinitis. He underwent a bilateral carotid endarterectomy procedure 2 years ago and had iliac artery angioplasty with stent placement 5 years ago for PVD. P.J.'s social history is significant for tobacco use (2 PPD) and alcohol (3–4 drinks/day). He is approximately 10 lb overweight. His preoperative laboratory results are significant for a total cholesterol of 270 mg/dL (desirable, <200), low-density lipoprotein cholesterol (LDL-C) of 163 mg/dL (optimal, <70), high-density lipoprotein cholesterol (HDL-C) of 35 mg/dL (low, <40), and triglycerides of 350 mg/dL (normal, <150). His medications before admission include atenolol 50 mg daily, aspirin 81 mg daily, isosorbide dinitrate 20 mg TID, atorvastatin 20 mg daily, fluticasone nasal spray (50 mcg/spray) 1 spray/nostril daily, and nitroglycerin 0.4 mg sublingually as needed. Which of P.J.'s chronic medical conditions may be caused or exacerbated by his tobacco use?

A wealth of evidence suggests that cigarette smoking is a major cause of cardiovascular disease and is responsible for approximately 128,000 premature cardiovascular-related deaths each year.[3,5,53]

There are numerous plausible pathophysiologic mechanisms by which tobacco smoking contributes to the development of cardiovascular disease.[7] Oxidant gases and other compounds in tobacco smoke are believed to induce a hypercoagulable state characterized by increased platelet aggregation and thrombosis, which substantially increases the risk of myocardial infarction (MI) and sudden death.[53,54] The carbon monoxide in smoke reduces the amount of oxygen available to tissues and organs, including myocardial tissue, and may reduce the ventricular fibrillation threshold.[53] Smoking may accelerate atherosclerosis through effects on serum lipids; smokers tend to have higher levels of total cholesterol, LDL-C, and triglycerides and lower HDL-C than nonsmokers.[3] Smoking increases the levels of inflammatory mediators (C-reactive protein, leukocytes, and fibrinogen), which might contribute to the development and progression of atherosclerosis.[55] Finally, smoking stimulates the release of neurotransmitters (e.g., epinephrine, norepinephrine) that increase myocardial workload and induce coronary vasoconstriction, leading to ischemia, arrhythmias, and sudden death.[3,53]

P.J.'s hospital admission for a CABG procedure for coronary heart disease and angina, and previous procedures for peripheral vascular disease (angioplasty with stent placement) and cerebrovascular disease (bilateral carotid endarterectomy) are all conditions associated with chronic tobacco use. His elevated total cholesterol, LDL-C, and triglycerides, and reduced HDL-C levels are consistent with smoking-induced dyslipidemia. Cigarette smoking in combination with P.J.'s other established cardiovascular risk factors (hypertension, dyslipidemia) has synergistically increased his risk for serious cardiovascular disease.[3,53] Fortunately, the effects of smoking on lipids, coagulation, myocardial workload, and coronary blood flow appear to be reversible, and P.J.'s risk of developing further cardiovascular-related complications will markedly decrease if he is able to quit smoking.[25,56]

Smoking cessation is associated with a 36% reduction in the risk of death among patients with established coronary heart disease. The reduced mortality risk associated with quitting smoking is comparable to that observed with other established secondary preventative approaches such as therapies for hyperlipidemia and hypertension.[57] The clinician should approach this hospitalization as an opportunity to assist P.J. with quitting smoking.[7] Furthermore, published data suggest that initiation of intensive cessation counseling interventions for hospitalized patients is effective in achieving long-term abstinence.[58]

Noncigarette Forms of Tobacco

CASE 91-2, QUESTION 2: The cardiothoracic surgeon has strongly advised P.J. to quit smoking. P.J. would like to know whether cutting down to one to two cigars a day is an acceptable alternative to his current one to two packs of cigarettes/day.

The adverse health effects of cigar smoking have been well described and include an increased risk of cancer of the lung, oral cavity, larynx, esophagus, and pancreas. In addition, cigar smokers who inhale deeply are at increased risk for developing cardiovascular disease and chronic obstructive pulmonary disease (COPD).[59,60] Cigarette smokers who switch to smoking only cigars decrease their risk of developing lung cancer, but their risk is markedly higher than if they were to quit smoking altogether.[60]

Cigar weight and nicotine content vary widely from brand to brand and from cigar to cigar. Most cigars range in weight from about 1 to 22 g, and a typical cigarette weighs less than 1 g. The nicotine content of 10 commercially available cigars studied in 1996 ranged from 10 to 444 mg. In comparison, US cigarettes have a relatively narrow total nicotine content range (mean, 13.5 ± 0.1 mg)/cigarette.[61] It is possible for one large cigar to contain as much tobacco as an entire pack of cigarettes and deliver enough nicotine to establish and maintain dependence.[62]

The amount of nicotine delivered by one to two cigars/day is capable of sustaining his dependence on nicotine. Furthermore, former cigarette smokers are more likely to inhale deeply, which further increases the risk of cancer and cardiovascular and pulmonary disease. The clinician should strongly advise P.J. to quit smoking cigarettes and that switching to cigars is not a safe alternative.

CASE 91-2, QUESTION 3: P.J. is willing to quit completely, but he is worried because he has tried to quit smoking "hundreds of times" and has never been able to quit for longer than 1 week. He expresses a desire for a medication to assist him during this quit attempt. He has tried the nicotine gum and transdermal patch during three previous quit attempts. He did not like the gum because it made his jaw sore. He had temporary success with the nicotine patch but found it to be less flexible than the gum. For example, when he needed extra nicotine during stressful situations, he could not apply a second patch. What treatment alternatives are reasonable for P.J.?

P.J. has inadequately responded to treatment with the transdermal patch and experienced intolerable jaw soreness with the nicotine gum. Newer formulations of the nicotine gum are less viscous, and therefore easier to chew, than earlier formulations of the gum; however, other options are available. First-line treatment options that he has not tried include the nicotine lozenge (see Case 91-1, Question 3), nicotine nasal spray, nicotine inhaler, sustained-release bupropion, varenicline, or an effective combination of first-line agents (see Case 91-3, Question 1).

Nicotine Nasal Spray

The nicotine nasal spray is an aqueous solution of nicotine available in a metered-spray pump for administration to the nasal mucosa. Each actuation delivers a metered 50-μL spray containing 0.5 mg of nicotine. Nicotine in the nasal spray is more rapidly absorbed than other NRT formulations (Fig. 91-3), with peak venous nicotine concentrations achieved within 11 to 18 minutes after administration.[14] Use of the nicotine nasal spray more than doubles long-term abstinence rates when compared with placebo).[7,35]

DOSING

Table 91-4 outlines the manufacturers' recommended dosing schedule for the nicotine nasal spray. A dose of nicotine (1 mg) is administered as two sprays, one (0.5-mg spray) in each nostril. For best results, patients should be encouraged to use at least eight doses/day during the initial 6 to 8 weeks of therapy because less frequent administration may be less effective. The initial regimen may be increased, as needed, to a maximum recommended dosage of five doses/hour or 40 mg/day. After 6 to 8 weeks, the dose should be gradually decreased during an additional 4 to 6 weeks.

PATIENT EDUCATION

Before using the nasal spray for the first time, the nicotine nasal spray pump must be primed. This is done by actuating the device into a tissue until a fine spray is visible (about 6–8 times). When administering a dose, the patient should tilt the head back slightly and insert the tip of the bottle into the nostril as far as is comfortable. After actuation of the pump, the patient should not sniff, swallow, or inhale through the nose because this increases the irritant effects of the spray. The spray increases the likelihood of tearing, coughing, and sneezing, so patients should wait 5 minutes before driving or operating heavy machinery.

ADVERSE REACTIONS

In clinical trials, 94% of patients report moderate–severe nasal irritation during the first 2 days of therapy; 81% of patients still reported mild to moderate nasal irritation after 3 weeks of therapy. Nasal congestion and transient changes in taste and smell have also been reported.[7] Despite the high incidence of local adverse effects (Table 91-4), most patients become tolerant to the irritant effects of the spray during the first week.[63]

PRODUCT SELECTION CONSIDERATIONS

The primary advantage in using the nicotine nasal spray is the ability to rapidly titrate therapy to manage withdrawal symptoms. However, because nicotine from the spray more rapidly penetrates the central nervous system, there may be a higher likelihood of developing dependence during treatment. The nicotine nasal spray has a dependence potential intermediate between tobacco products and other NRT products. Individuals with chronic nasal disorders (e.g., rhinitis, polyps, sinusitis) or severe reactive airway disease should not use the nicotine nasal spray because of its irritant effects. Exacerbation of asthma has been reported after use of the nicotine nasal spray.[64]

Nicotine Inhaler

The nicotine oral inhaler consists of a plastic mouthpiece and a disposable cartridge containing a porous plug containing 10 mg of nicotine and 1 mg of menthol. Menthol is added to reduce the irritant effect of nicotine.

Given that the usual pack-a-day smoker repeats the hand-to-mouth motion up to 200 times per, it is not surprising that many smokers find they miss the physical manipulation of the cigarette and associated behaviors that accompany smoking. The nicotine inhaler was designed to provide nicotine replacement in a manner similar to smoking while addressing the sensory and ritualistic factors that are important to many patients who smoke.[36]

As a patient inhales through the mouthpiece, nicotine vapor is released from the cartridge and is distributed throughout the oral cavity. When the inhaler is used correctly, approximately 4 mg of nicotine vapor is released from the cartridge and 2 mg is absorbed across the buccal mucosa.[65] Peak plasma nicotine concentrations with the inhaler are achieved after approximate 30 minutes of use[14] and then slowly decline thereafter (Fig. 91-3). Use of the nicotine inhaler approximately doubles long-term abstinence rates when compared with placebo (Table 91-4).[7,35]

DOSING

Table 91-4 outlines the manufacturers' recommended dosing schedule for the nicotine inhaler. During the initial 3 to 6 weeks of treatment, the patient should use 1 cartridge every 1 to 2 hours while awake. This should be increased, as needed, to a maximum of 16 cartridges/day. The manufacturer recommends that each cartridge be depleted of nicotine by frequent continuous puffing for 20 minutes. The recommended duration of treatment is 3 months, after which patients may be weaned from the inhaler by gradual reduction of the daily dose during the following 6 to 12 weeks.

PATIENT EDUCATION

To minimize the likelihood of throat irritation, patients should be instructed to inhale shallowly (as if puffing a pipe). When used correctly, 100 shallow puffs from the inhaler mouthpiece during 20 minutes approximate 10 puffs from one cigarette during 5 minutes.[36] The release of nicotine from the inhaler is temperature dependent and significantly reduced at temperatures less than 40°F.[7,36] In cold conditions, patients should store the inhaler and cartridges in a warm place (e.g., inside pocket).[7] Conversely, under warmer conditions, more nicotine is released/puff. However, nicotine plasma concentrations achieved using the inhaler in hot climates at maximal doses will not exceed levels normally achieved with smoking.[36]

As with all forms of NRT that are absorbed across the buccal mucosa, the effectiveness of the nicotine inhaler is reduced by acidic foods and beverages, such as coffee, juices, wine, or soft drinks. Therefore, patients should be instructed not to eat or drink anything (except water) for 15 minutes before or while using the inhaler.

ADVERSE REACTIONS

The most common side effects associated with the nicotine inhaler include mouth or throat irritation (40%) and cough (32%).[7] Most patients rated cough and mouth and throat irritation symptoms as mild, decreasing with continued use. Other less common side effects are rhinitis, dyspepsia, hiccups, and headache. Adverse reactions necessitating discontinuation of treatment occurred in less than 5% of patients using the inhaler.

PRODUCT SELECTION CONSIDERATIONS

Patients who express a preference for therapy that can be easily titrated to manage withdrawal symptoms or one that mimics the hand-to-mouth ritual of smoking may find the nicotine inhaler to be an appealing option. Patients with underlying bronchospastic conditions should use the nicotine inhaler with caution, because the nicotine vapor can be irritating and might induce bronchospasm.

Sustained-release Bupropion

Sustained-release bupropion increases long-term abstinence rates relative to placebo. (RR 1.62; Table 91-4).[7,43]

DOSING

Because approximately 1 week of treatment is necessary to achieve steady state blood levels, sustained-release bupropion should be initiated while the patient is still smoking (Table 91-4). Patients should set a target quit date that falls within the first 2 weeks of treatment, generally in the second week. The starting dose of sustained-release bupropion is one 150-mg tablet each morning for the first 3 days. If the initial dose is tolerated, the dosage should be increased on the fourth day to the recommended maximal dosage of 300 mg/day (150 mg BID). Therapy should be continued for 7 to 12 weeks after the quit date.

PATIENT EDUCATION

Patients experiencing insomnia should avoid taking the second dose close to bedtime. Patients should be informed that bupropion might cause dizziness or drowsiness, and should exercise caution when driving or operating machinery. Patients should avoid or drink alcohol only in moderation while taking bupropion as alcohol use can increase the risk of seizures. Abrupt cessation of alcohol use while taking bupropion might increase the risk of seizure. Patients should also be advised not to take Zyban[66] and Wellbutrin or generic bupropion formulations concomitantly to avoid dose-related adverse effects, including seizures.

ADVERSE REACTIONS

The most common adverse effects associated with bupropion therapy include insomnia (35%–40%) and dry mouth (10%)[8]; these usually lessen with continued use. Taking the second daily dose in the early evening, but no sooner than 8 hours after the first dose, might reduce insomnia. Less common side effects include headache, nausea, tremors, and rash. Seizures are a dose-related toxicity associated with bupropion therapy. For this reason, bupropion is contraindicated in patients with underlying seizure disorders and those receiving concurrent therapy with other forms of bupropion (Wellbutrin, Wellbutrin SR, and Wellbutrin XL). Bupropion also is contraindicated in patients with anorexia or bulimia nervosa, patients undergoing abrupt discontinuation of alcohol or sedatives (including benzodiazepines), and patients currently taking monoamine oxidase inhibitors owing to the increased potential for seizures in these populations.[67] In clinical trials for smoking cessation, seizure frequency with sustained-release bupropion was less than 0.1% (seven seizures among 8,000 bupropion-treated patients), which is comparable to the reported incidence of seizures (0.1%) with the sustained-release formulation when used for the treatment of depression.[68] For this reason, bupropion should be used with extreme caution in patients with a history of seizures or cranial trauma, in individuals taking medications that may lower the seizure threshold, and in patients with underlying severe hepatic cirrhosis. The manufacturer recommends that patients space the doses at least 8 hours apart and limit the total daily dose to no more than 300 mg. Although a boxed warning has been removed, clinicians should monitor patients for serious psychiatric symptoms while taking bupropion.

PRODUCT SELECTION CONSIDERATIONS

Sustained-release bupropion may be the drug of choice for patients who prefer to take oral medications (an alternative oral option is varenicline, described below). Because sustained-release bupropion tablets require twice daily administration, this agent may be preferable for patients with adherence concerns (e.g.,

---

those unable to consistently use short-acting NRT formulations that require multiple daily doses). Sustained-release bupropion might be beneficial for use in patients with coexisting depression or in individuals with a history of depressive symptoms during a previous quit attempt. Finally, sustained-release bupropion has been found to reduce postcessation weight gain during treatment,[7,52] and this might be of short-term benefit in selected patients with concerns about weight gain after quitting. Disadvantages of sustained-release bupropion include a high prevalence of insomnia and several contraindications and precautions mentioned above.

Varenicline

Data from meta-analyses indicate that varenicline significantly increases long-term abstinence rates relative to placebo,[7,46] NRT,[46] and sustained-release bupropion.[7,46] The pooled risk ratio for long-term abstinence (≥6 months) for varenicline compared with placebo was 2.24 (95% CI, 2.06-2.43). The pooled risk ratio for varenicline versus sustained-release bupropion at 1-year follow-up was 1.39 (95% CI, 1.25 - 1.54). At 24 weeks, the pooled risk ratio for varenicline compared to NRT was 1.25 (95% CI, 1.14 -1.37).[46] Lower doses and longer durations of varenicline have been shown to be safe and effective in clinical trials.[46]

PHARMACOKINETICS

Varenicline absorption is virtually complete after oral administration, and oral bioavailability is unaffected by food. Once absorbed, varenicline undergoes minimal metabolism, with 92% excreted unchanged in the urine. Renal elimination is primarily through glomerular filtration, along with active tubular secretion.[69] The half-life is approximately 24 hours, and following administration of multiple oral doses, steady state conditions are reached within 4 days.[69]

DOSING

Treatment with varenicline (Table 91-4) should be initiated 1 week before the patient stops smoking. This dosing regimen allows for gradual titration of the dose to minimize treatment-related nausea and insomnia. The recommended dosage titration for varenicline is as follows: 0.5 mg daily days 1 to 3, 0.5 mg twice daily days 4 to 7, and 1 mg twice daily weeks 2 to 12. For patients who have successfully quit smoking at the end of 12 weeks, an additional course of 12 weeks may be considered to increase the likelihood of long-term abstinence. An alternative approach is to set a quit date 8 to 35 days after starting varenicline. Patients should be advised to decrease their smoking over the first 12 weeks and then continue varenicline for 12 additional weeks.[69] Varenicline should be used with caution in patients with impaired renal function. For patients with severe renal dysfunction (estimated creatinine clearance <30 mL/minute), the recommended maximal dose of varenicline is 0.5 mg twice daily. In patients with end-stage renal disease undergoing hemodialysis, a maximal dose of 0.5 mg daily is recommended.[69]

PATIENT EDUCATION

The tablets are to be taken after eating and with 8 ounces of water. Nausea and insomnia are side effects that are usually temporary. Patients should be advised to discontinue varenicline and contact their healthcare provider immediately if they experience agitation, hostility, depressed mood, or changes in behavior or thinking that are not typical for them (see adverse reactions below).

ADVERSE REACTIONS

Varenicline is generally well tolerated. Common side effects (≥5% and twice the rate observed in placebo-treated patients) include nausea (30%), sleep disturbance (insomnia 18%; abnormal dreams 13%), constipation (8%), flatulence (6%), and vomiting (5%). Nausea is dose dependent and generally described as mild or moderate and often transient; however, for some patients, it persists for several months. Initial dose titration was beneficial in reducing the occurrence of nausea. Approximately 3% of subjects receiving varenicline 1 mg BID discontinued treatment prematurely because of nausea. For patients with intolerable nausea, dose reduction should be considered.[69]

The FDA recommends that (a) patients tell their healthcare providers about any history of psychiatric illness before starting varenicline, and (b) clinicians and patients monitor for changes in mood and behavior during treatment with varenicline.[69] A large, randomized, controlled trial that included a cohort of smokers with current or past psychiatric disorders evaluated the neuropsychiatric safety of varenicline, bupropion, nicotine patch, and placebo. No difference in neuropsychiatric adverse events was reported between groups.[70] Additionally, a review of published cases and clinical trials using varenicline in patients with schizophrenia and schizoaffective disorder concluded that psychiatric symptoms were not worsened significantly in stable, carefully monitored patients with these conditions.[71] The prescribing information for varenicline was revised to include warning for a possible increased risk of cardiovascular events (MI, ischemic and hemorrhagic stroke) in patients with stable cardiovascular disease.[69] However, a published meta-analyses examining the risk concluded that there is no significant increase in the risk of serious cardiovascular events with varenicline in tobacco cessation.[72] Seizures have been reported in patients treated with varenicline, most often within the first month of therapy. These events occurred in individuals who had no seizure history, as well as in those with a remote history or well-controlled seizure disorder.[69]

PRODUCT SELECTION CONSIDERATIONS

Varenicline is a first-line agent for the treatment of tobacco use and dependence.[7,23] It offers a convenient oral dosing regimen and a new mechanism of action that might be particularly appealing for patients who have failed quit attempts with other first-line agents (e.g., NRT or sustained-release bupropion). Given its potential for inducing negative neuropsychiatric effects, varenicline should be used with extreme caution in patients with a current or past history of psychiatric illness.

P.J. has tried the nicotine gum and transdermal patch during previous quit attempts. Because he was intolerant to the nicotine gum (sore jaw), this form of NRT is not appropriate. P.J.'s experience with the transdermal patch suggests he may benefit from a short-acting NRT formulation that enables active administration and titration of drug as needed to alleviate symptoms of withdrawal and situational cravings. Other first-line therapies include the nicotine nasal spray, inhaler, and lozenge; sustained-release bupropion; or varenicline. P.J. should not use the nicotine nasal spray because he has allergic rhinitis and may be more susceptible to the irritant effects of the spray. In addition, some data suggest that the bioavailability of nicotine is reduced in patients with rhinitis.[63] Furthermore, the safety and efficacy of the nasal spray in patients with chronic nasal disorders have not been adequately studied.

Reasonable choices for P.J. therefore include sustained-release bupropion, nicotine lozenge, nicotine inhaler, or varenicline. Any of these options are reasonable, and the choice of therapy should be dictated by P.J.'s individual preference. If varenicline is chosen, given P.J. has underlying cardiovascular disease, he should be instructed to notify a healthcare provider for new or worsening cardiovascular symptoms and to seek immediate medical attention if he experiences signs and symptoms of myocardial infarction. Finally, it is reasonable to consider combination therapy (see Case 91-3, Question 1).

Safety of Nicotine Replacement Therapy Among Patients with Cardiovascular Disease

CASE 91-2, QUESTION 4: P.J. would like to try the nicotine inhaler. Is NRT safe for use in patients with cardiovascular disease?

Nicotine activates the sympathetic nervous system, leading to an increase in heart rate, blood pressure, and myocardial contractility. Nicotine also may cause coronary artery vasoconstriction.[74] These known hemodynamic effects of nicotine have led to doubts about the safety of using NRT in patients with established cardiovascular disease, particularly those with serious arrhythmias, unstable angina, or recent MI.

Soon after the nicotine patch was approved, anecdotal case reports in the lay press linked NRT (patch and gum) with adverse cardiovascular events (i.e., arrhythmias, MI, stroke). Since then, several randomized, controlled trials have evaluated the safety of NRT in patients with cardiovascular disease.[75–77] The results of these trials suggest no significant increase in the incidence of cardiovascular events or mortality among patients receiving the nicotine patch when compared with placebo. However, because these trials specifically excluded patients with unstable angina, serious arrhythmias, and recent MI, the manufacturers of NRT products recommend that these agents be used with caution among patients in the immediate (within 2 weeks) post-MI period, those with serious arrhythmias, and those with unstable angina.[7]

Although two small, retrospective studies have raised questions regarding the safety of NRT use in intensive care settings,[77,78] NRT use in patients with cardiovascular disease has been the subject of numerous reviews, and it is widely believed by experts in the field that the risks of NRT in this patient population are small in relation to the risks of continued tobacco use.[2,53,72,74,75] The 2008 Clinical Practice Guideline concludes that there is no evidence of increased cardiovascular risk with these medications.[7] Although the use of NRT may pose some theoretic risk in a patient like P.J., cigarette smoking is far more hazardous to his health. Cigarettes, unlike NRT, deliver numerous toxins that induce a hypercoagulable state, reduce the oxygen-carrying capacity of hemoglobin, and adversely affect serum lipids. The amount of nicotine that P.J. would receive using the recommended dose of any NRT product will not exceed the amount he previously obtained from his 2 PPD smoking habit. The clinician should strongly encourage pharmacotherapy during P.J.'s current quit attempt. P.J. is 10 lb overweight; the additional risk imposed by a modest weight gain after smoking cessation likely will not be of clinical significance compared with that of continued smoking.

Combination Therapy for Tobacco Dependence

CASE 91-3

QUESTION 1: J.B. is a 60-year-old man referred to the pulmonary clinic for further evaluation and management of his chronic obstructive pulmonary disease (COPD). He complains of decreased exercise tolerance and has noted increasing shortness of breath (SOB) with minimal exertion (e.g., while golfing or climbing stairs). He currently uses an albuterol inhaler (90 mcg/puff), 2 puffs every 4 hours regularly for SOB. His medical history is otherwise unremarkable except for osteoarthritis controlled with acetaminophen 1 g TID. He has smoked approximately 1.5 to 2 PPD for more than 40 years. J.B. indicates he has made several quit attempts during the past year. On the first attempt (quitting "cold turkey"), J.B. relapsed within 2 days. J.B. successfully quit for nearly 2 weeks on his second attempt (using the 4-mg nicotine lozenge), but he found it difficult to adhere to the frequent dosing schedule and relapsed shortly after discontinuing the lozenge. His most recent quit attempt was 6 months ago using varenicline. After 1 month of abstinence, J.B. self-terminated varenicline (I thought I didn't need it anymore) and relapsed within 1 week. On further questioning, J.B. states that he did not enroll in a behavioral counseling program or seek additional assistance (other than pharmacotherapy) during any of his quit attempts. He expresses an interest in smoking cessation but is discouraged by his prior lack of success. On physical examination, coarse breath sounds that clear after coughing are noted. A chest radiograph obtained in the office shows no infiltrates. J.B. is concerned about his worsening pulmonary function and is committed to making another effort to quit. What treatment options are appropriate for J.B.?

Tobacco smoking is the single most important risk factor for the development of COPD,[3] and nearly all patients diagnosed with COPD are current or former smokers.[79] Given his escalating pulmonary symptoms, it is imperative that he stop smoking as soon as possible. J.B. should be advised that medications for COPD offer only limited symptomatic relief, and the most important component of his treatment is smoking cessation.[79,80] The clinician should commend J.B. for his interest in quitting and help him devise a patient-specific treatment plan.

Plasma levels of nicotine achieved with standard doses of NRT are generally much lower than those attained with regular smoking.[63,81] As such, conventionally dosed NRT may deliver subtherapeutic nicotine levels for some individuals, and in particular, for moderate-to-heavy smokers.

Combination NRT regimens, which typically consist of a long-acting agent (nicotine patch) in combination with a short-acting formulation (i.e., gum, lozenge, inhaler, or nasal spray), are often used as initial therapy. The long-acting formulation, which delivers nicotine at a relatively constant level, is used to prevent the onset of severe withdrawal symptoms, and the short-acting formulation, which delivers nicotine at a more rapid rate, is used as needed to control withdrawal symptoms that may occur during potential relapse situations (e.g., after meals, during times of stress, when around other smokers).

Controlled trials suggest that the nicotine patch in combination with short-acting NRT formulations (i.e., gum, lozenge, nasal spray, or inhaler) significantly increase quit rates relative to placebo. Similar results have been observed in trials using combination therapy with sustained-release bupropion and the nicotine patch. Aggressive combination regimens including triple-agent NRT (e.g., patch, inhaler, and nasal spray) with or without sustained-release bupropion, triple-combination therapy (e.g., patch, inhaler, and sustained-release bupropion)[82] may be a safe and effective treatment approach. Some data suggest that adding varenicline alone[83] or sustained-release bupropion and varenicline to nicotine patch,[84,85] therapy may improve cessation rates; however, addition of bupropion sustained-release to varenicline had little effect on long-term abstinence and increased rates of depression and anxiety.[85]

Clinicians should be aware that although the combination of the nicotine patch and sustained-release bupropion has been approved by the FDA, the concurrent use of multiple NRT products is not FDA-approved for tobacco cessation. Furthermore, the optimal agents, dosages, and durations of therapy for NRT combination therapy are currently unknown.

Given the severity of J.B.'s condition and his willingness to quit now, the clinician should initiate treatment as soon as possible. His treatment should consist of pharmacotherapy in conjunction with behavioral counseling and appropriate follow-up.

PHARMACOTHERAPY

The clinician should work with J.B. to select the most appropriate pharmacotherapy. As noted previously, appropriate options would include the various NRT formulations, sustained-release bupropion, varenicline, or an effective combination of first-line agents. For patients reporting a positive experience with a given medication, retreatment with the same agent or a combination of agents might be appropriate, with consideration given to increasing the dose, frequency, or duration of therapy. For patients reporting a negative experience with pharmacotherapy (e.g., poor adherence, side effects, palatability issues, cost), an alternative agent should be considered. Given J.B.'s previous adherence issues with the nicotine lozenge as monotherapy, it might be preferable to use a long-acting cessation medication such as the nicotine patch, sustained-release bupropion, or varenicline. Combination therapy might also be appropriate.

BEHAVIORAL COUNSELING

Although medications are effective alone in helping patients quit smoking, the combination with pharmacotherapy maximizes patients' chances for a long-term, successful quit attempt. J.B.'s previous 1-month-long quit attempt highlights the success of varenicline in this patient; however, J.B.'s relapse likely is attributable to a shortened course of therapy and the absence of a behavioral change program. J.B. should be advised that the medications are designed to make patients more comfortable while quitting and that behavioral counseling is needed to address the "habit" of smoking by helping him cope with difficult situations and triggers for relapse. J.B. should be advised to JB should be advised to pursue behavioral therapy options in addition to pharmacotherapy. J.B. should be reminded that adherence with the medication regimen—daily adherence, as well as duration of therapy—will increase his chances of quitting for good. Clinician-delivered counseling might also include a personalized message to further enhance his motivation to quit. For example, the clinician could perform pulmonary function testing and translate J.B.'s spirometry results into an effective "lung age" (e.g., the age of the average healthy individual with similar spirometry values). This educational approach has been found to significantly increase long-term (12-month) quit rates in a recent controlled trial.[86]

Drug Interactions with Smoking

CASE 91-4

QUESTION 1: M.K. is a new patient requesting Ortho Cyclen (norgestimate/ethinyl estradiol). The new patient history form completed by M.K. reveals that she is 32 years old, weighs 65 kg, and is 70 inches tall. She takes no prescription medications but occasionally uses loratadine 10 mg as needed for allergies, and ibuprofen 400 mg as needed for dysmenorrhea. She has no significant medical history. Her father has hypertension and suffered an MI last year. Her mother has type 2 diabetes and dyslipidemia. Her social history is significant for tobacco use (1 PPD for 15 years), alcohol (1 glass of wine/night), and caffeine (3–4 cups of coffee daily). Are there any potential drug interactions with M.K.'s new prescription?

SMOKING AND COMBINED HORMONAL CONTRACEPTIVES

One of the most important precautions to consider with oral contraceptive use is the potential interaction between tobacco smoke and estrogens in combination hormonal contraceptives (see Chapter 47, Contraception). Estrogens are known to promote coagulation by altering clotting factor levels and increasing platelet aggregation. As described in Case 91-2, Question 1, substances present in tobacco smoke induce a hypercoagulable state, increasing the risk of acute cardiovascular events. Exposure to both factors (smoking and high levels of estrogen) greatly increases the risk of thromboembolic and thrombotic disorders. Considerable epidemiologic evidence indicates that cigarette smoking substantially increases the risk of adverse cardiovascular events, including stroke, MI, and thromboembolism in women who use oral combination hormonal contraceptive agents.[87,88] This risk is age-related, in that the absolute risk of death as a result of cardiovascular disease in oral contraceptive users who smoke is 3.3/100,000 women ages 15 to 34 years compared with 29.4/100,000 women ages 35 to 44 years. To put this in perspective, the corresponding risk of death as a result of cardiovascular disease in nonsmoking women who use oral contraceptives is much lower, with a death rate of 0.65/100,000 women ages 15 to 34 years and 6.21/100,000 women ages 35 to 44 years.[89] Because of the increased risk of adverse cardiovascular events, current guidelines[89] state that combination estrogen–progestin contraceptives should not be used in women who are older than 35 years of age and smoke, and progestin-only or nonhormonal contraceptives are recommended for use in this population. M.K. is 32 years of age, and despite smoking 20 cigarettes/day, oral contraceptive use is not contraindicated at this time. However, the clinician should strongly advise M.K. to quit smoking and assess her readiness to do so. M.K. should be informed that if she continues to smoke while using oral combined hormonal contraceptives, her risk of developing a blood clot, stroke, or heart attack will continue to increase with time.

ALTERNATIVE THERAPIES

CASE 91-4, QUESTION 2: M.K. asks whether e-cigarettes or vapes are effective for smoking cessation.

Some patients or clinicians may ask about the efficacy of electronic nicotine delivery systems (ENDS) in tobacco cessation. These devices seem to offer an attractive solution in that they may eliminate exposure to the toxic substances inhaled when tobacco is burned in cigarettes. Little data are available to support use of ENDS as a tobacco-cessation therapy. A systematic review concluded that ENDS may help smokers successfully stop smoking, although more robust data on the safety and efficacy of ENDS are needed.[90] Preliminary data suggest that adding ENDS use to cigarettes does not increase cessation.[91] Data are unclear on the safety of ENDS as a cessation method, although to date few adverse events have been reported.[90, 91] M.K. should be advised that the efficacy of ENDS as cessation therapies is not well established, and use of these agents cannot be recommended at this time.

Although many herbal and homeopathic products are available to help people quit smoking, data that support their safety and efficacy are lacking. Furthermore, patients should be cautioned that herbal cigarettes are not safe alternatives because they result in the inhalation of other toxins present in smoke.

CASE 91-4, QUESTION 3: M.K. is not considering quitting smoking in the next 30 days. She cannot discontinue her oral contraceptives because she is sexually active and needs a reliable form of birth control. She wonders whether the new low-dose birth control pills or other formulations (e.g., patch, vaginal ring) are safer for smokers.

Combined oral contraceptives available in the United States contain estrogen in doses ranging from 20 to 50 mcg of ethinyl estradiol. Higher doses of ethinyl estradiol appear to have greater procoagulant effects.[92–94]

In 2001, the US Surgeon General stated that lower-dose oral contraceptives may be associated with a reduced risk for coronary

---

heart disease (CHD) compared with higher-dose formulations. Despite this conclusion, the report cautioned that heavy smokers who use oral contraceptives still have a greatly elevated risk for CHD.[94]

Serum estrogen levels obtained with the vaginal ring are significantly lower than those achieved with either transdermal or oral combined contraceptive formulations, and data have not shown the patch or the ring to be safer options for women who smoke. Current guidelines apply the same precautions to all contraceptives containing estrogen.[89]

M.K.'s prescribed oral contraceptive agent (Ortho Tri-Cyclen) contains 35 mcg of ethinyl estradiol in combination with 0.25 mg norgestimate. Although some clinicians recommend the use of low-dose (20 mcg) estrogen preparations in smokers, the available evidence suggests that the prescribed regimen poses no additional risk in M.K. The clinician should inform M.K. that there are currently no studies demonstrating a reduced risk of adverse cardiovascular events in smokers using oral contraceptives containing low doses (e.g., 20 mcg) of estrogen or the newer transdermal and vaginal ring formulations.[95] In the absence of published data, only smoking cessation can be advocated to definitively reduce the risk of stroke, MI, and thromboembolism in women who use combined hormonal contraceptives.

BEHAVIORAL COUNSELING

Although M.K. is not considering quitting at this time, it is appropriate for the clinician to apply the 5 R's (Table 91-2) to promote motivation to quit. This counseling should be relevant to M.K.'s situation and should highlight the risks of continued tobacco use, such as her elevated risk for thromboembolic and thrombotic disorders (associated with continued use of oral contraceptives). M.K. should be asked to think about the rewards of quitting and any potential roadblocks to quitting. At subsequent encounters, the clinician should sensitively assess M.K.'s tobacco use status and motivation to quit, and offer assistance with quitting when M.K. is ready. If M.K. decides to quit, it would be important to reassess her caffeine intake because caffeine, which is metabolized via CYP450 1A, levels have been reported to increase by 56% in patients who quit smoking.[21]

Brief Interventions to Promote Tobacco Cessation

CASE 91-5

QUESTION 1: J.C. is a 52-year-old man with a history of asthma requesting a refill of his albuterol inhaler prescription. This is the third request for an albuterol inhaler (200 doses/inhaler) during the past 2 months. Before this period, his last refill was more than a year ago. J.C. reports that he has been using albuterol on most days of the week for coughing and SOB. He has no other medical conditions and takes no other medications. His social history is significant for tobacco use (smokes 1.5 PPD; he recently started smoking again after starting a new job where "everyone smokes"). J.C. previously quit smoking 20 years ago using the "cold turkey" approach (e.g., no medications or counseling), and although he was successful, he was miserable for weeks and he expresses reluctance to "go through this again" during a stressful job transition.

The clinician is running behind schedule and does not have the time to provide comprehensive smoking-cessation counseling during this patient encounter. What brief smoking-cessation interventions can the clinician provide to J.C. to assist him with quitting?

TELEPHONE QUITLINES

Clinicians should become aware of local, community-based resources for tobacco cessation, including telephone quitlines. When time or expertise does not afford provision of comprehensive tobacco-cessation counseling during a patient visit, clinicians are encouraged to apply a truncated 5 A's model, whereby they ask about tobacco use, advise tobacco users to quit, and refer patients who are ready to quit to a telephone quitline. Effective brief interventions can generally be accomplished in fewer than 3 minutes. Telephone services provide low-cost interventions that can reach patients who might otherwise have limited access to medical treatment because of geographic location or lack of insurance or financial resources. Data support the efficacy of quitline counseling in promoting abstinence.[30,32] The addition of medication to quitline counseling significantly improves abstinence rates compared with medication alone.[7] In addition, preliminary evidence suggests that quitlines are also effective for smokeless tobacco cessation.[96] The telephone number for the toll-free tobacco quitline is 1-800-QUIT NOW.

J.C.'s asthma is not well controlled (e.g., increased use of short-acting bronchodilator). The change in J.C.'s asthma control is temporally related to his recent job change and relapse to daily smoking. Exposure to tobacco smoke is a potent trigger for asthma exacerbations and an important cause of poor asthma control. Given that the clinician is unable to provide comprehensive smoking-cessation counseling at this time, a brief intervention is appropriate. The clinician should strongly advise J.C. to quit as a key component of his asthma management plan and refer him to a telephone quitline or to other resources that are available within the community (e.g., local individual or group counseling programs). The clinician should briefly explain that pharmacologic treatment combined with support should increase the likelihood of a successful quit attempt compared to his previous, "cold turkey" experience. clinician could address J.C.'s previous negative experience with quitting by educating on the benefits of medications in reducing nicotine withdrawal symptoms.

Smoking Among Individuals with Mental Illness

CASE 91-6

QUESTION 1: J.D. is a 42-year-old woman presenting to clinic for follow-up of her depression management. Nine months ago, she was started on venlafaxine XR 75 mg daily. At her 3-month follow-up visit, she was stable on venlafaxine XR 150 mg daily, and her depressive symptoms had improved. She also reported that she was sleeping much better. J.D. has no other significant past medical history, and she takes no other medications. Her social history is positive for current tobacco use (1 PPD for 25 years) and caffeine use (1–2 Diet Cokes a day). She does not drink alcohol. During the appointment, J.D. indicates that she would like to quit smoking because her depression is better, and she knows that her overall health will improve if she quits. She also states that the last time she attempted to quit (several years ago, using the nicotine gum), she felt "down and had difficulty concentrating and couldn't sleep." She is now fearful that her depression will return if she quits. Is smoking cessation appropriate for J.D. at this time, and what are her treatment options?

Although persons with mental illness constitute 20% of the US population, nearly 36% smoke cigarettes.[9] In the past, the mental health community has not addressed smoking cessation with their patients, but increasing evidence suggests that quitting is possible and should be promoted. For patients with mental

illness to achieve wellness, smoking-cessation intervention is an essential component of the overall care plan.[97]

Given that J.D. is currently willing to quit, and her depression has been stabilized for more than 4 months, it is appropriate for the clinician to discuss a quitting plan with J.D. and initiate therapy. The therapeutic approach should include counseling and pharmacotherapy, with ongoing monitoring of progress toward quitting and depressive symptoms.

TREATMENT SELECTION

Pharmacotherapy

Because no contraindications are present, any of the FDA-approved medications for cessation are appropriate. Although data are mixed on efficacy of varenicline in patients with psychiatric illness,[98] varenicline seems to be safe. In a pooled analysis of patients without psychiatric disorders, only sleep disorders and disturbances exhibited a higher incidence in patients treated with varenicline.[98]

Regardless of whether sustained-release bupropion, varenicline, or NRT product(s) are selected, the clinician should monitor J.D. closely to assess incidence of depressive symptomatology. If sustained-release bupropion or varenicline is selected, J.D. should be advised to stop taking the medication and contact the clinician immediately if she experiences agitation, depressed mood, and any changes in behavior that are not typical of nicotine withdrawal, or if she experiences suicidal thoughts or behavior.

BEHAVIORAL COUNSELING

Because J.D. has indicated that she is ready to quit, the clinician should commend her for making the important decision that will positively impact her overall health. J.D. should be advised that quitting is a process, and it will be important for them to work closely together to address the physiologic as well as psychological aspects of quitting during the upcoming months.

CASE 91-6, QUESTION 2: After discussing the various treatment options with the clinician, J.D. decides that she would like to add sustained-release bupropion to her regimen because the nicotine gum by itself did not help her much last time. She also thinks that the combination of venlafaxine with bupropion might help to “keep her depression more stable” whereas she is quitting. She confides in the clinician that her biggest fear is the ability to avoid smoking when she is stressed because of her job. She is a survey researcher and must meet client-induced deadlines. How can J.D. cope with stressful situations?

A variety of coping mechanisms can be applied to alleviate the need to smoke during stressful situations or when exposed to other triggers for smoking (Table 91-3). The clinician should encourage J.D. to think about strategies that would be effective for her in these situations, such as deep breathing or calling a supportive friend. Additionally, the clinician should consider suggesting use of a short-acting NRT product (e.g., nicotine gum, lozenge, inhaler, or nasal spray) as needed to alleviate situational cravings to smoke. Appropriate dosing of sustained-release bupropion should be reviewed (Table 91-4). A follow-up appointment should be scheduled for approximately 3 months after the quit date, and the patient should be advised to contact the clinician if she encounters any difficulties before then.

CASE 91-6, QUESTION 3: Four weeks later, J.D. calls and reports that she has a dry mouth, is having difficulty sleeping, and feels jittery and anxious. She also is currently using nicotine gum (2 mg), approximately four pieces daily. How should J.D. be managed?

As noted above, insomnia and dry mouth are commonly associated with sustained-release bupropion therapy and usually lessen with continued use.[67] The nicotine gum dose is low and not likely contributing to this condition. To address insomnia, J.D. can be advised to take the second dose of the day earlier, but not less than 8 hours after the first dose of the day. Alternatively, the clinician could consider reducing the daily dose to 150 mg in the morning and omitting the evening dose. Although the manufacturer recommends 300 mg/day, the 150-mg dose has been shown to have comparable outcomes with those of the 300-mg dose and is better tolerated.[99, 100] The clinician also should assess J.D.’s caffeine consumption patterns and, if appropriate, suggest that she reduce her caffeine intake by 50% and not drink caffeinated beverages after 12 noon so her system is clear of its stimulatory properties before sleep.[22]

Extended-Use Medications for Cessation

CASE 91-6, QUESTION 4: J.D. returns to the clinician's office 3 months later and indicates that she is doing well but had a few "slips" and smoked four times. She has not felt depressed and has been handling her stress at work through deep-breathing exercises. She uses the nicotine gum a few times a week and does not feel ready to discontinue the sustained-release bupropion. She wonders whether it is possible to continue the therapy for a bit longer, until she feels more stable as a nonsmoker.

Extended-duration medication therapy appears to be safe and effective. Long-term follow-up data indicate that approximately 15% of long-term quitters continued nicotine gum therapy with no serious side effects.[101] The 2008 Clinical Practice Guideline states that extended use of medications might be beneficial in individuals who report persistent withdrawal symptoms during treatment, those who have relapsed shortly after medication discontinuation, or those who are interested in long-term therapy.[7]

Clinicians should be aware that although many of the medications (sustained-release bupropion, varenicline, nicotine nasal spray, and inhaler) are approved by the FDA for long-term (6-month) use, the effectiveness of additional weeks on therapy is not well established. A meta-analysis of eight trials found that extended treatment with varenicline might prevent relapse, extended treatment with bupropion is unlikely to have a clinically important effect, and studies of extended treatment with nicotine replacement are needed.[102] Given J.D.'s current depression and because she is interested in continuing therapy, it is reasonable for the clinician to recommend continuation of therapy for an additional 12 weeks and reassess progress at that time. If JD does decide to discontinue her bupropion, then it should be with close monitoring by her mental health professional to assess for any rebound depressive symptoms.

Anemias

Cindy L. O'Bryant, Ashley E. Glode, and Lisa A. Thompson

CORE PRINCIPLES		CHAPTER CASES
1	Anemias arise from multiple etiologies. A full laboratory evaluation is necessary to appropriately diagnose and determine the cause of anemia.	**Case 92-1 (Questions 1, 2), Case 92-2 (Question 1), Case 92-5 (Question 2), Figure 92-1, Table 92-2 and 92-3**
2	Iron deficiency is the most common nutritional deficiency worldwide and is associated with symptoms of pallor, cardiovascular, respiratory, cognitive complications, and decreased quality of life.	**Case 92-1 (Question 2)**
3	Oral or parenteral iron is used to treat iron deficiency anemia. The goal of therapy is an increased hemoglobin of 1 to 2 g/dL within 2 to 4 weeks of the initiation of therapy.	**Case 92-1 (Questions 1, 3-5, 7–9), Table 92-6 and 92-8**
4	Distinguishing between vitamin B_{12}-deficient and folic acid-deficient megaloblastic anemia is important to minimize potentially permanent effects of these deficiencies.	**Case 92-2 (Questions 1, 2), Case 92-3 (Question 1), Case 92-5 (Questions 1, 2)**
5	Patients with sickle cell disease should receive appropriate preventive care, including infection prophylaxis with penicillin and routine immunizations.	**Case 92-6 (Questions 1, 2)**
6	Acute sickle cell crises are an urgent situation and should be managed with pain control, transfusions, oxygen, or antibiotic therapy as appropriate.	**Case 92-7 (Questions 1–3)**
7	Anemia of inflammation is associated with the upregulation of inflammatory cytokines that results in shortened red blood cell survival and decreased production. Treatment focuses on the underlying disease and the use of erythropoietin (EPO).	**Case 92-8 (Question 1)**
8	Response to EPO depends on the dose and underlying cause of anemia. Lack of response to treatment with erythropoiesis-stimulating agents (ESAs) is commonly associated with functional or absolute iron deficiency. Safety concerns with the use of ESAs have resulted in a Risk Evaluation and Mitigation Strategy (REMS) program for the use of these agents.	**Case 92-8 (Question 1)**

ANEMIAS

Definition

Anemia is a reduction in red blood cell (RBC) mass. It is often described as a decrease in the number of RBCs per microliter (μL) or as a decrease in the hemoglobin (Hgb) concentration in blood to a level below the normal physiologic requirement for adequate tissue oxygenation. The term anemia is not a diagnosis, but rather an objective sign of a disease. Diagnostic terminology for anemia requires the inclusion of the pathogenesis (e.g., megaloblastic anemia secondary to folate deficiency, microcytic anemia secondary to iron deficiency) in order to implement the appropriate specific therapy to correct the anemia.

Pathophysiology

Anemia is a symptom of many pathologic conditions. It is associated with nutritional deficiencies, acute and chronic diseases, and may be drug-induced. Anemia is also caused by decreased RBC production, increased RBC destruction, or increased RBC loss. When anemia is caused by decreased RBC production, it may be the result of disturbances in stem cell proliferation or differentiation. Anemias caused by increased RBC destruction can be secondary to hemolysis, whereas increased RBC loss may be caused by acute or chronic bleeding. Anemias associated with acute blood loss, those that are iron-related, and those caused by inflammation constitute most anemias.[1] Classifications of anemias according to pathophysiologic and morphologic characteristics are shown in Table 92-1.

Table 92-1

Classifications of Anemia

Pathophysiologic (Classifies Anemias Based on Pathophysiologic Presentation)
Blood Loss
Acute: trauma, ulcer, hemorrhoids Chronic: ulcer, vaginal bleeding, aspirin ingestion
Inadequate Red Blood Cell Production
Nutritional deficiency: vitamin B_{12}, folic acid, iron
Erythroblast deficiency: bone marrow failure (aplastic anemia, irradiation, chemotherapy, folic acid antagonists) or bone marrow infiltration (leukemia, lymphoma, myeloma, metastatic solid tumors, myelofibrosis)
Endocrine deficiency: pituitary, adrenal, thyroid, testicular

Chronic disease: renal, liver, infection, granulomatous, collagen vascular
Excessive Red Blood Cell Destruction
Intrinsic factors: hereditary (G6PD), abnormal hemoglobin synthesis Extrinsic factors: autoimmune reactions, drug reactions, infection (endotoxin)
Morphologic (Classifies Anemias by Red Blood Cell Size [Microcytic, Normocytic, Macrocytic] and Hemoglobin Content [Hypochromic, Normochromic, Hyperchromic])
Macrocytic
Defective maturation with decreased production
Megaloblastic: pernicious (vitamin B_{12} deficiency), folic acid deficiency
Normochromic, Normocytic
Recent blood loss
Hemolysis
Chronic disease
Renal failure
Autoimmune
Endocrine
Microcytic, Hyperchromic
Iron deficiency
Genetic abnormalities: sickle cell, thalassemia

G6PD, glucose-6-phosphate dehydrogenase.

Normally, RBC mass is maintained by feedback mechanisms that regulate levels of erythropoietin (EPO), a hormone that stimulates proliferation and differentiation of erythroid precursors in the bone marrow. Two types of erythroid precursors reside in the bone marrow: the burst forming unit–erythrocyte cell (BFUe) and colony forming unit–erythrocyte cell (CFUe). The BFUe is the earliest progenitor, which eventually develops into a CFUe. The BFUe is moderately sensitive to EPO and is under the influence of other cytokines (e.g., interleukin [IL] 3, granulocyte-macrophage colony-stimulating factor [GM-CSF]). In contrast, the CFUe is highly sensitive to EPO and differentiates into erythroblasts and reticulocytes. The kidneys produce 90% of EPO; liver synthesis accounts for the remainder. Reduced oxygen-carrying capacity is sensed by renal peritubular cells, which stimulates release of EPO into the bloodstream. Patients with chronic anemia may have a blunted and inadequate EPO response for the degree of anemia present.

Detection

SIGNS AND SYMPTOMS

Signs and symptoms of anemia vary with the degree of RBC reduction as well as with the time to development. The decreased oxygen-carrying capacity of the reduced RBC mass results in tissue hypoxia followed by decreased perfusion to nonvital tissues (e.g., skin, mucous membranes, extremities) in order to sustain tissue perfusion of vital organs (e.g., brain, heart, kidneys). Slowly developing anemias can be asymptomatic initially or include symptoms such as slight exertional dyspnea, increased angina, fatigue, or malaise.[1,2]

In severe anemia (Hgb <8 g/dL), heart rate and stroke volume often increase in an attempt to improve oxygen delivery to tissues. These changes in heart rate and stroke volume can result in systolic murmurs, angina pectoris, high-output heart failure, pulmonary congestion, ascites, and edema. Thus, anemia is generally not well tolerated in patients with cardiac disease. Skin and mucous membrane pallor, jaundice, smooth or beefy tongue, cheilosis, and spoon-shaped nails (koilonychia) also may be associated with severe anemia of different etiologies.

HISTORY

A thorough history, including a time line of onset of symptoms and current clinical status, and physical examination are essential because of the complexity of the pathologic conditions associated with anemia. When evaluating a patient for the diagnosis of anemia, histories should include: (a) past and current Hgb or hematocrit (Hct) values; (b) transfusion history; (c) family history, because longstanding anemias can indicate hereditary disorders; (d) occupational, environmental, and social histories; and (e) medication history, to eliminate drug reactions or interactions as the cause of the anemia.

PHYSICAL EXAMINATION

Pallor is most easily observed in the conjunctiva, mucous membranes, nail beds, and palmar creases of the hand. In addition, postural hypotension and tachycardia can be seen when hypovolemia (acute blood loss) is the primary cause of anemia. Patients with vitamin B_{12} deficiency may exhibit neurologic findings consistent with nerve fiber demyelination, which may include changes in deep tendon reflexes, ataxia, and loss of vibration and position sense. Patients with anemia from hemolysis may be slightly jaundiced from bilirubin release. Manifestations of hemorrhage can include petechiae, ecchymoses, hematomas, epistaxis, bleeding gums, and blood in the urine or the stool.

LABORATORY EVALUATION

Although anemia may be suspected from the history and physical examination, a full laboratory evaluation is necessary to confirm the diagnosis, establish severity, and determine the cause. A list of the routine laboratory evaluations used in the workup for anemia is found in Table 92-2. The cornerstone of this evaluation is the complete blood count (CBC). Other evaluations assessing nutritional deficiencies, including iron studies, vitamin B_{12}, and folate as well as EPO levels may also provide insight into the cause of anemia as shown in Table 92-3. Males have higher normal Hgb and Hct values than do females. The Hgb and Hct are increased in individuals living at altitudes greater than 4,000 feet in response to the diminished oxygen content of the atmosphere and blood.

Table 92-2

Routine Laboratory Evaluation for Anemia Workup

Complete blood count (CBC): Hgb, Hct, RBC count, RBC indices (MCV, MCH, MCHC), WBC count (and differential)
Platelet count
RBC morphology
Reticulocyte count
Bilirubin and LDH
Serum iron, TIBC, serum ferritin, transferrin saturation
Peripheral blood smear examination
Stool examination for occult blood
Bone marrow aspiration and biopsy[a]

[a] Performed in patients with abnormal peripheral blood smears.

Hgb, hemoglobin; Hct, hematocrit; RBC, red blood cell; MCV, mean corpuscular volume; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; WBC, white blood cell; RBC, red blood cell; LDH, lactate dehydrogenase; TIBC, total iron-binding capacity.

The morphologic appearance of the RBC found in RBC indices included as part of the CBC, including mean corpuscular volume (MCV), mean cell Hgb (MCH), and mean cell Hgb concentration (MCHC), provide useful information about the nature of the anemia. Note: corpuscular and cell may be used interchangeably when referring to MCV, MCH, etc. Microscopic evaluation of the peripheral blood smear can detect the presence of macrocytic (large) RBCs, which are associated with vitamin B_{12} or folic acid deficiency, or microcytic (small) RBCs, typically associated with iron deficiency anemia. Acute blood loss generally is associated with normocytic cells.

Table 92-3

Supplemental Hematology Values

	Pediatric	Adult	
Laboratory Test	**1–15 years**	**Male**	**Female**
Erythropoietin (milliunits/mL)	4–26	4–26	4–26
Reticulocyte count (%)	0.5–1.5	0.5–1.5	0.5–1.5
TIBC (mg/dL)	250–400	250–400	250–400
Fe (mg/dL)	50–120	50–160	40–150
Fe/TIBC (%)	20–30	20–40	16–38

Ferritin (ng/mL)	7–140	15–200	12–150
Folate (ng/mL)	7–25	7–25	7–25
RBC folate (ng/mL)	—	140–960	140–960
Vitamin B_{12} (pg/mL)	>200	>200	>200

Fe, iron; RBC, red blood cell; TIBC, total iron-binding capacity.

The history and physical examination and laboratory evaluation typically provide sufficient information to distinguish among the most common forms of anemia (Fig. 92-1). If not identified after routine evaluation, problems such as autoimmune disease, collagen vascular disease, chronic infection, or endocrine disorders may be causing the anemia. When uncertainty exists or an abnormal peripheral blood smear is noted, a bone marrow aspiration with biopsy is indicated.

Iron Deficiency Anemia

Figure 92-1 Laboratory diagnosis of anemia.

There are many causes of anemia. This chapter is limited to the most common anemias and their medication management. Hemolytic anemias will not be discussed. Before proceeding, the reader should review the basic hematologic laboratory tests used to evaluate and monitor anemia (see Chapter 2, Interpretation of Clinical Laboratory Tests).

IRON DEFICIENCY ANEMIA

Iron deficiency is a state of negative iron balance in which the daily iron intake and stores are unable to meet the RBC and other body tissue needs.[3] This is not the same as iron-deficient erythropoiesis, which is a decreased supply of plasma iron to the marrow for RBC synthesis, which can occur with normal or elevated amounts of stored iron. The body contains approximately 3 to 4 g of iron, of which 2.5 g is found in RBCs.[4,5] Only a small fraction of iron is found in plasma and most is bound to transferrin, the transport protein.[4]

Despite the continuing turnover of RBCs, iron stores are well preserved because the iron is recovered and reused in new erythrocytes. Only about 1 to 2 mg/day of iron is lost from minor bleeding, urine, sweat, and the sloughing of intestinal mucosal cells that contain ferritin in men and in nonmenstruating women.[4] Menstruating women lose approximately an additional 1 mg of iron per day.[6] Pregnancy and lactation are other common sources of iron loss (see Chapter 49, Obstetric Drug Therapy).

Individuals with normal iron stores absorb roughly 10% of ingested dietary iron. The average American diet contains 5 to 15 mg of elemental iron and 1 to 5 mg of heme iron, resulting in 1 to 2 mg of absorbed iron from the intestines. For menstruating, pregnant, or lactating women, however, the daily iron intake requirement may be as high as 20 to 30 mg.[7]

Iron is absorbed from the duodenum and upper jejunum by an active transport mechanism. Dietary iron exists primarily in the ferric state and is converted to the more readily absorbed ferrous form in the acidic environment of the stomach. The ferrous form binds to transferrin for transport to the bone marrow, where it is incorporated into the Hgb of mature erythrocytes.

Gastrointestinal (GI) absorption of iron is increased as much as three- to fivefold in iron deficiency states or when erythropoiesis occurs at a more rapid rate.[6] Animal sources of iron (heme iron) are better absorbed than plant sources (nonheme iron). A number of issues, including gastrointestinal diseases, surgical bypass, a hypochloric state, infections, or drug–food complexes, can alter the absorption of iron.[7] Anemia caused by iron deficiency is the most common nutritional deficiency worldwide.[6] Although iron deficiency anemia has many causes (Table 92-4), blood loss is considered one of the more common. Common causes of chronic blood loss include peptic ulcer disease, hemorrhoids, ingestion of GI irritants, menstruation, multiple pregnancies, and multiple blood donations.[8]

Dietary reference intakes (DRI) for iron are listed in Table 92-5.[9,10] The increased amounts of iron required by pregnant or lactating women are difficult to obtain through diet alone; thus, oral iron supplementation generally is necessary. Although maternal iron usually provides term infants with sufficient stored iron for the first 6 months, infants 6 months to 3 years of age experience rapid growth and a threefold increase in blood volume, which can increase the risk of iron deficiency. Premature infants have reduced iron stores and thus require replacement therapy.

Table 92-4

Iron Deficiency Anemia Causes[8]

Blood Loss
Menstruation, gastrointestinal (e.g., peptic ulcer), trauma, blood donation
Decreased Absorption
Medications, gastrectomy, bariatric surgery, celiac, regional enteritis
Increased Requirement
Infancy, pregnant/lactating women, adolescence
Impaired Utilization
Hereditary, iron use
Environmental
Insufficient intake, diet (e.g., vegetarian)

Table 92-5

Dietary Reference Intake for Iron[9,10]

	mg/day
Healthy, nonmenstruating adults	8
Menstruating women	18
Pregnant women	27
Lactating women	9
Vegetarians	16[a]
Preterm Infants	2–4
Term Infants (Birth to 6 months)	0.27
Term Infants (7–12 months)	11
Toddlers (1–3 years)	7

[a] Twofold higher than those not consuming a vegetarian diet.

Predisposing Factors

CASE 92-1

QUESTION 1: H.P. is a 31-year-old woman seen in the clinic. Her chief complaints include weakness, dizziness, and epigastric pain. She has a 5-year history of peptic ulcer disease, a 10-year history of heavy menstrual bleeding, and a 15-year history of chronic headaches. She has two children who are 1 and 3 years of age. H.P. is currently taking minocycline 100 mg twice daily (BID) for acne, ibuprofen 400 mg as needed for headaches, and esomeprazole 40 mg daily. Her review of systems is positive for decreased exercise tolerance. Physical examination reveals a pale, lethargic, white woman appearing older than her stated age. Her vital signs are within normal limits; her heart rate is regular at 100 beats/minute. Her examination is notable for pale nail beds and splenomegaly.

Significant laboratory results include the following:

Hgb, 8 g/dL
Hct, 26%
Platelet count, 500,000/μL
Reticulocyte count, 0.2%
MCV, 75 femtoliters (fL)
MCH, 23 pg/cell
MCHC, 300 g/L
Serum iron, 40 mcg/dL
Serum ferritin, 9 ng/mL

Total iron-binding capacity (TIBC), 450 g/dL
4+ stool guaiac (normal, negative)

Iron deficiency is determined to be the cause of H.P.'s anemia. An upper GI series with a small bowel follow-through are planned to evaluate her persistent epigastric pain.

What factors predispose H.P. to iron deficiency anemia?

Several factors predispose H.P. to iron deficiency anemia. Her history of heavy menstrual bleeding and the 4+ stool guaiac indicate menstrual and GI sources of blood loss. The GI blood loss may be secondary to H.P.'s chronic use of nonsteroidal anti-inflammatory drugs, recurrent peptic ulcer disease, or both.

Many women of childbearing age have a borderline iron deficiency that becomes more evident during pregnancy because of the increased iron requirements.[3] H.P. has given birth to two children. Therefore, her iron stores have been repeatedly taxed in recent years. In addition, absorption of dietary iron may be compromised by her use of proton pump inhibitors and minocycline (see Case 92-1, Question 6).

Signs, Symptoms, and Laboratory Tests

CASE 92-1, QUESTION 2: What subjective or objective signs, symptoms, and laboratory tests are typical of iron deficiency in H.P.?

H.P.'s constitutional symptoms of weakness and dizziness could be a result of her severe anemia. Generally, until the anemia is severe, such symptoms occur with equal frequency in the nonanemic population. The most important signs and symptoms of iron deficiency anemia are related to the cardiovascular system and are a reflection of the imbalance between the ongoing demands for oxygen against a diminishing oxygen supply.

H.P.'s increased heart rate, decreased exercise tolerance, and pale appearance are consistent with tissue anoxia and the cardiovascular response that may be seen in iron deficiency anemia. H.P.'s iron deficiency has advanced to symptomatic anemia. In patients who are not yet symptomatic, however, depletion of iron stores can be detected by measuring ferritin, the iron storage compound. Although ferritin is primarily an intracellular protein, serum concentrations of ferritin correlate closely with iron stores with only a few exceptions.[7] Ferritin, an acute-phase reactant, is generally found in higher levels in patients with inflammatory disorders, infection, malignancy, liver disease, and chronic renal failure.[3,7] H.P. has a serum ferritin level of 9 ng/mL; less than 12 ng/mL is consistent with iron deficiency. An increased TIBC also can reflect depletion of storage iron, but it is less sensitive than serum ferritin. Thus, in iron deficiency, the serum ferritin concentration is low, whereas the TIBC is usually high; both of these parameters can be detected before the clinical manifestations of anemia are apparent. These abnormalities persist and worsen because anemia develops as illustrated by H.P.'s laboratory values. If the TIBC is low or normal, rather than high, in association with a low serum ferritin, other causes of anemia should be considered and evaluated with additional labs and bone marrow examination.

H.P.'s low serum iron, low serum ferritin, and elevated TIBC are typical of the laboratory findings associated with iron deficiency anemia. Serum transferrin receptor levels, which reflect the amount of RBC precursors available for active proliferation, are increased in iron deficiency. After stored iron is depleted, heme and Hgb synthesis is decreased. In severe iron deficiency, the RBCs become hypochromic (low MCHC) and microcytic (low MCV).[5]

Usually, the RBC indices do not become abnormal until the Hgb concentration falls to less than 10 g/dL. H.P.'s corpuscular indices indicate that her anemia is hypochromic and microcytic.

The reticulocyte count provides an estimate of effective RBC production and is usually normal or low in iron deficiency anemia. H.P. has a reticulocyte count of 0.2%, which also is compatible with iron deficiency anemia.

In the workup of a microcytic, hypochromic anemia, the stool should be examined for occult blood. H.P. has a 4+ stool guaiac, which suggests blood loss via the GI tract. Further diagnostic evaluations (e.g., endoscopy, abdominal X-rays) are necessary to determine the underlying problem. In summary, H.P.'s signs, symptoms, and laboratory findings all support the diagnosis of an iron deficiency anemia.

Iron Therapy

ORAL IRON DOSING

CASE 92-1, QUESTION 3: How should H.P.'s iron deficiency be managed? What dose of iron should be given to treat H.P.'s iron deficiency anemia?

The primary treatment for H.P. should be directed toward control of the underlying causes of anemia; GI blood loss, multiple childbirths, heavy menstrual flow, decreased dietary iron absorption, and perhaps, an inadequate diet. The cause of her GI blood loss should be corrected, her dietary intake should be analyzed and modified and supplemental iron should be prescribed to replenish her stores and correct the anemia.

The usual adult dose of ferrous sulfate is 325 mg (one tablet) administered 3 times daily between meals. However, because of limited absorption of iron in the intestines, repletion with lower doses of iron has been shown to be effective, potentially minimizing side effects and improving compliance.[7] If no iron is being lost through bleeding, the required daily dose of elemental iron can be calculated using a formula that assumes that 0.25 g/dL/day is the maximal rate of Hgb regeneration.

$$\text{Elemental iron (mg/day)} = 0.25\text{g Hgb}/100\text{ mL blood}/\text{day}\ (5{,}000\text{ mL blood})(3.4,\text{ mg Fe}/1\text{ g Hgb}) \qquad \text{(Eq. 92-1)}$$

$$\begin{aligned}
&= 40\text{ mg Fe}/\text{day}/20\%\text{ absorption (approximate absorption rate in iron-deficient states)}\\
&= 200\text{ mg Fe}/\text{day}\\
&= 1{,}000\text{ mg ferrous sulfate}/\text{day (ferrous sulfate contains 20\% elemental iron)}\\
&= 325\text{ mg 3 times daily (TID) ferrous sulfate} \qquad \text{(Eq. 92-2)}
\end{aligned}$$

PRODUCT SELECTION

CASE 92-1, QUESTION 4: What are the differences between iron products? Which is the product of choice?

The ferrous form of iron is absorbed 3 times more readily than the ferric form. Although ferrous sulfate, ferrous gluconate, and ferrous fumarate are absorbed almost equally, each contains a different amount of elemental iron that is available for absorption.[11] Carbonyl iron, another iron product, is available but its use may be limited owing to the fact that iron in this form must be solubilized by gastric acid to be absorbed. Table 92-6 compares the iron content of several oral iron preparations to assist in making appropriate treatment choices for patients.

Product Formulation

Product formulation is of considerable importance in product selection. Sustained release (SR) and enteric coated preparations may increase GI tolerance or decrease side effects, increase bioavailability, and also may have additives claimed to enhance absorption. Because these products can be given once daily, increased adherence is an additional claim.

Table 92-6

Comparisons of Oral Iron Preparations[11]

Preparation	Dose (mg)	Fe^{2+} Content (mg)	Fe (%)
Ferrous sulfate	325	65	20
Ferrous fumarate	324	106	33
Ferrous gluconate	240	29	12
Carbonyl iron	—	45	—
Ferrous sulfate (time-released)	160	50	32

Note: This is a representative list of example oral iron preparations that may be utilized.

Anecdotal claims that SR iron preparations cause fewer GI side effects have not been substantiated by controlled studies. These products transport iron past the duodenum and proximal jejunum, thereby reducing the absorption of iron.[5,7] Because poor absorption and poor hematologic responses might occur with SR formulations, caution should be used if chosen for initial treatment.

Adjuvants are incorporated into iron preparations in an attempt to enhance absorption or mitigate side effects. An acidic environment is needed for absorption in the duodenum and upper jejunum. Ascorbic acid (vitamin C), given in doses up to 1 gram, is able to increase iron absorption by approximately 7%; however, smaller doses of vitamin C (e.g., 25 mg) do not significantly alter iron absorption.[12] To decrease the side effect of constipation, stool softeners are also sometimes added to iron preparations.[5] The stool softener dose may not be appropriate and additional doses may need to be taken. In summary, H.P. should take the least expensive iron preparation containing ferrous sulfate, gluconate, or fumarate.

GOALS OF THERAPY

CASE 92-1, QUESTION 5: What are the goals of iron therapy? How long should H.P. be treated? How should H.P. be monitored?

The goals of iron therapy are to normalize the Hgb and Hct concentrations and to replete iron stores. Initially, if the doses of iron are adequate, the reticulocyte count will begin to increase by the 3rd to 4th day and peak by the seventh to 10th day of therapy. By the end of the second week of iron therapy, the reticulocyte count will fall back to normal. The Hgb response is a convenient index to monitor in outpatients. Hematologic response is usually seen in 2 to 3 weeks with a 1 to 2 g/dL increase in Hgb and a 6% increase in the hematocrit. H.P.'s anemia can be expected to resolve in 1 to 2 months; however, iron therapy should be continued for 3 to 6 months after the Hgb is normalized to replete iron stores.[7] Therapy duration is related to the absorption pattern of iron with more iron being absorbed during the first month of therapy; because iron stores are repleted, less is absorbed.

PATIENT INFORMATION

CASE 92-1, QUESTION 6: What information should be provided to H.P. when dispensing oral iron? What can be done if she experiences intolerable GI symptoms (e.g., nausea, epigastric pain)?

Iron should be dispensed in a childproof container and H.P. should be counseled to store it in a safe place, inaccessible to her young children. Accidental ingestion of oral iron can cause serious consequences in small children[13] (see Chapter 5, Managing Drug Overdoses and Poisoning). H.P. should be told that oral iron therapy produces dark stools. She should try to take her iron on an empty stomach because food, especially dairy products, decreases the absorption by up to 50%.[11]

Gastric side effects, which occur in 5% to 20% of patients, include nausea, epigastric pain, constipation, abdominal cramps, and diarrhea. Constipation does not appear to be dose-related but side effects (e.g., nausea and epigastric pain) occur more frequently because the quantity of soluble elemental iron in contact with the stomach and duodenum increases.[5] To minimize gastric intolerance, oral iron therapy can be initiated with a single tablet of ferrous sulfate 325 mg/day and increased by increments of one tablet per day every 2 to 3 days until the full therapeutic dose of 325 mg 3 times daily can be administered.

H.P. also should be educated about potential drug interactions that can occur with iron therapy. Currently, she is taking a proton pump inhibitor, which is thought to inhibit serum iron absorption by increasing the pH of the stomach and decreasing the solubility of ferrous salts. In addition, antacids can increase stomach pH, and certain anions (carbonate and hydroxide) also are thought to form insoluble complexes when combined with iron. Table 92-7 provides additional drug interactions to be considered.

H.P. is also taking minocycline for the treatment of acne. Because the absorptions of both iron and minocycline are decreased when administered concomitantly, the minocycline should be taken at least 2 hours apart.[11]

PARENTERAL IRON THERAPY

Indications

CASE 92-1, QUESTION 7: When would parenteral iron therapy be indicated for H.P.?

Several indications exist for parenteral iron administration. Causes of oral therapy failure can include nonadherence, misdiagnosis, inflammatory conditions, malabsorption (e.g., atrophic gastritis, radiation enteritis, gastric bypass, celiac disease), the need for rapid iron repletion, and continuing blood loss equal to or greater than the rate of RBC production.[3,4] Besides failure to respond to oral therapy, other indications for parenteral iron administration include intolerance to oral therapy, required antacid therapy, or significant blood loss in patients refusing transfusion. In H.P.'s case, intolerance, continued blood loss, long-term antacid therapy, and malabsorption may be potential indications for use and, if documented, she would be a candidate for injectable iron.

Preferred Route

CASE 92-1, QUESTION 8: What is the preferred formulation of parenteral iron administration?

Iron can be given parenterally in the form of ferric gluconate, iron dextran, iron sucrose, ferric carboxymaltose, and ferumoxytol (Table 92-8).[14] Comparison between agents reveals similar efficacy with differences in cost analysis from diverse administration schedules. Iron dextran and ferric carboxymaltose are US Food and Drug Administration (FDA)-approved for the treatment of iron deficiency when oral supplementation is impossible or ineffective. All parenteral iron products can be administered undiluted slowly as an intravenous (IV) push, or diluted and administered by infusion; although not included in the FDA-approved labeling, iron dextran injection is commonly diluted in 500 mL of 0.9% NaCl and administered by IV infusion.[3] Iron dextran is also the only product that may be given intramuscularly (IM). This route may be preferred in a few instances, such as in patients with limited IV access. Although the data are limited, infusion of the total dose (total estimated iron deficit) of iron dextran is given in clinical practice and has proved to be effective and convenient.[15] The total dose method of administration can be associated with a higher prevalence of fever, malaise, flushing, and myalgias. Because of the potential for anaphylaxis with iron dextran, an IM or IV test dose should be given. The test dose for adults is 25 mg of iron dextran. Although anaphylactic reactions usually are evident within a few minutes if they occur, it is recommended that a period of 1 hour or longer elapse before the remaining portion of the initial dose be given. Subsequent use of test doses should be considered during iron dextran therapy but is not required.

Table 92-7

Drug Interactions with Iron Salts

Iron Salts Drug Interactions

Precipitant drug	Object drug[a]		Description
Acetohydroxamic acid (AHA)	Iron salts	↓	AHA chelates heavy metals, notably iron. The absorption of iron may be decreased. When iron is indicated, administer intramuscularly (IM).
Antacids	Iron salts	↓	GI absorption of iron may be reduced.
Ascorbic acid	Iron salts	↑	Ascorbic acid at doses ≥200 mg have been shown to enhance the absorption of iron ≥30%.
Calcium salts	Iron salts	↓	GI absorption of iron may be reduced. When possible, separate administration times.
Chloramphenicol	Iron salts	↑	Serum iron levels may be increased.
Digestive enzymes	Iron salts	↓	The serum iron response to oral iron may be decreased by concomitant pancreatic extracts.
H_2 antagonists	Iron salts	↓	GI absorption of iron may be reduced.
Proton pump inhibitors	Iron salts	↓	GI absorption of iron may be reduced.
Trientine	Iron salts	↓	The 2 agents inhibit the absorption of each other. If iron is needed, administer the agents at least 2 hours apart.
Iron salts	Trientine		
Iron salts	Captopril	↓	Concomitant use within 2 hours may promote formation of inactive captopril disulfide dimer.
Iron salts	Cephalosporins (e.g., cefdinir)	↓	Iron supplements and foods fortified with iron may reduce the absorption of cefdinir 80% and 30%, respectively. If iron supplements are needed during cefdinir therapy, cefdinir should be taken 2 hours before or after the supplement. Iron-fortified infant formula (elemental iron 2.2 mg per 6 oz) has no effect on cefdinir absorption.
Iron salts	Fluoroquinolones (e.g., ciprofloxacin)	↓	GI absorption of fluoroquinolones may be decreased because of formation of iron–quinolone complex. Avoid coadministration of these drugs. (See individual fluoroquinolone monographs for administration recommendations.)
Iron salts	Levodopa	↓	Levodopa appears to form chelates with iron salts, decreasing levodopa absorption and serum levels.
Iron salts	Levothyroxine	↓	The efficacy of levothyroxine may be decreased, resulting in hypothyroidism. Avoid coadministration.
Iron salts	Methyldopa	↓	Extent of methyldopa absorption may be decreased, possibly resulting in decreased efficacy.
Iron salts	Mycophenolate mofetil	↓	Absorption of mycophenolate mofetil may be decreased. Avoid simultaneous administration.
Iron salts	Penicillamine	↓	Marked reduction in GI absorption of penicillamine may occur, possibly because of chelation.
Iron salts	Tetracyclines	↓	Concomitant use within 2 hours may decrease absorption and serum levels of tetracyclines. Absorption of iron salts also may be decreased.
Tetracyclines	Iron salts		
Iron salts	Thyroid hormones	↓	Absorption of thyroid hormones may be decreased. Avoid coadministration.

[a] ↑ = object drug increased; ↓ = object drug decreased.

Ferric gluconate, iron sucrose, and ferumoxytol are parenteral iron formulations that are FDA-approved for the treatment of iron deficiency anemia in patients with chronic kidney disease undergoing chronic hemodialysis. Ferric carboxymaltose is indicated for treatment of iron deficiency anemia in nondialysis-dependent chronic kidney disease. A test dose is not required for these agents due to the lower incidence of serious anaphylactoid reactions. Iron requirements in these patients typically exceed 1 to 2 g and, therefore, multiple doses of ferric gluconate and iron sucrose are needed to achieve the total dose of iron.

Table 92-8

Comparison of Parenteral Iron Preparations

Preparation	Dosage Form	Usual Dose	Maximum Dose
Ferric carboxymaltose	Solution for injection: 50 mg/mL (elemental iron)	Weight ≥50 kg: 750 mg per dose Weight <50 kg: 15 mg/kg per dose Repeat dose ≥7 days	1,500 mg (cumulative per treatment course)
Ferumoxytol	Solution for injection: 30 mg/mL (elemental iron)	510 mg per dose; repeat once 3–8 days later	N/A
Iron dextran	Solution for injection: 50 mg/mL (elemental iron)	Test dose: 25 mg; followed by up to 75 mg (dose based on patient weight)	100 mg per day
Iron sucrose	Solution for injection: 20 mg/mL (elemental iron)	**HD:** 100 mg during consecutive HD sessions for 10 doses **CKD, nondialysis:** 200 mg on 5 different occasions over 14 days; 500 mg once on days 1 and 14 **CKD, PD:** 300 mg IV days 1 and 14, then 400 mg on day 28	N/A
Sodium ferric gluconate complex	Solution for injection: 12.5 mg/mL (elemental iron)	125 mg per dose (usually repeated to cumulative dose of 1,000 mg)	N/A

CKD: chronic kidney disease; HD: hemodialysis; PD: peritoneal dialysis.

In general, rates of adverse effects are similar among agents. Patients should be monitored for hypersensitivity reactions for at least 30 minutes after administration of any parenteral iron compound.

Dosage Calculation

CASE 92-1, QUESTION 9: What is the total dose of iron dextran for IV infusion that would be needed to achieve a normal Hgb value for H.P. and to replenish her iron stores? How quickly should she respond?

The total dose of iron dextran to be administered can be determined using the following equation.

$$\text{Iron (mg)} = \text{Weight (pounds)} \times 0.3\ \{100 - [100(\text{Hgb})/14.8]\} \qquad \text{(Eq. 92-3)}$$

where Hgb is the patient's measured Hgb (g/dL).

The equation uses the person's weight (in pounds) and assumes that an Hgb of 14.8 g/dL is 100% of normal. Children weighing less than 30 pounds should be given 80% of the calculated dose because the normal mean Hgb in this population is lower.

For patients with anemia resulting from blood loss (e.g., hemorrhagic diathesis) or patients receiving chronic dialysis, the iron requirement is based on the estimate of iron contained in the blood lost. In this case, the following equation should be used:

$$\text{Iron (mg)} = \text{Blood loss (mL)} \times \text{Hct (the patient's measured Hct expressed as a decimal fraction)} \qquad \text{(Eq. 92-4)}$$

This formula assumes that 1 mL of normochromic blood contains 1 mg of iron.

After parenteral administration, iron dextran is cleared by the reticuloendothelial cells and processed. The iron is then released back into the plasma and bone marrow. Because the rate of iron incorporation into Hgb does not exceed that achieved by oral iron therapy, the response time is similar to that of oral iron therapy, and the Hgb can be expected to increase at a rate of 1 to 2 g/dL/week during the first 2 weeks and by 0.7 to 1 g/dL/week thereafter until normal values are attained.

Side Effects

CASE 92-1, QUESTION 10: What side effects can be expected from parenteral iron therapy?

Overall adverse reactions reported with parenteral iron administration are rare.[16] Anaphylactoid reactions occur in less than 1% of patients treated with parenteral iron therapy and are more commonly associated with iron dextran and ferumoxytol than with ferric gluconate and iron sucrose.[16,17] In a small study comparing iron dextran to ferric carboxymaltose, patients experienced significantly fewer immune-related adverse reactions.[18] Other side effects seen with parenteral iron agents include chest pain, headache, hypotension, nausea and vomiting, cramps, and diarrhea.

MEGALOBLASTIC ANEMIAS

Megaloblastic anemia is a common disorder that can have several causes, including anemias associated with vitamin B_{12} or folic acid deficiency or metabolic or inherited defects associated with a decreased ability to use vitamin B_{12} or folic acid.[19,20]

Megaloblastosis results from impaired DNA synthesis in replicating cells, which is signaled by a large immature nucleus.[19] RNA and protein synthesis remain unaffected, and the cytoplasm matures normally. Megaloblastic changes can be observed microscopically in RBC and in proliferating cells (e.g., in the cervix, skin, GI tract). The extent of RBC macrocytosis is reported as MCV, calculated as shown below.

$$\text{MCV (fL)} = [\text{Hct (percent)} \times 10]/[\text{RBC count } (10^6/\mu\text{L})] \tag{Eq. 93-5}$$

Although the clinical effects of vitamin B_{12} and folic acid deficiencies can differ in various organ systems, they are similar in their effects on the hematopoietic system. Typically, macrocytic anemia develops slowly and can be identified by large, oval, well-hemoglobinized RBCs; anisocytosis; and nuclear remnants. The reticulocyte count is low and the bilirubin level is elevated. If biopsied, the bone marrow is markedly hypercellular. Nuclear immaturity is present, but the megaloblasts have normal maturation of the cytoplasm. Iron stores in the marrow are increased as a result of the intramedullary hemolysis. Symptoms include fatigue; exaggeration of preexisting cardiovascular or pulmonary problems; a sore, pale, smooth tongue; diarrhea or constipation; and anorexia.[21,22]

Vitamin B_{12} Deficiency Anemia

VITAMIN B_{12} METABOLISM

Deficiency and poor utilization of vitamin B_{12} are two mechanisms for the development of megaloblastic anemia.[22] Vitamin B_{12} (cobalamin) is naturally synthesized by microorganisms, but humans are incapable of doing so and must obtain vitamin B_{12} in their diet. Animal protein and fortified foods provide the majority of dietary vitamin B_{12}.[23] The typical Western diet contains 3.5 to 5 mcg/day of vitamin B_{12}, an amount sufficient to replace the up to 1 mcg lost daily through urine, sweat, and other body secretions.

In the stomach, vitamin B_{12} is released from protein complexes and bound to intrinsic factor, which protects it from degradation by GI microorganisms. Intrinsic factor is essential for the absorption of vitamin B_{12}. Specific mucosal receptors in the distal small ileum allow for attachment of the intrinsic factor–vitamin B_{12} complex. Vitamin B_{12} is then transferred to the ileal cell and finally to portal vein blood.

After vitamin B_{12} is absorbed, it is bound to specific β-globulin transport proteins, transcobalamins I, II, and III. Transcobalamin II is responsible for transporting absorbed vitamin B_{12} through cell membranes and delivering it to the liver and other organs. In the liver, vitamin B_{12} is converted to coenzyme B_{12}, which is essential for hematopoiesis, maintenance of myelin throughout the entire nervous system and production of epithelial cells.

Total body stores of vitamin B_{12} range from 2,000 to 3,000 mcg, approximately 50% of which is stored in the liver. Because body stores are extensive, 5 to 10 years are required before symptoms of vitamin B_{12} deficiency develop.[21]

PATHOGENESIS AND EVALUATION OF VITAMIN B_{12} DEFICIENCY

Vitamin B_{12} deficiency can result from decreased supply (reduced intake, absorption, transport, or utilization) or increased requirement (greater metabolic consumption, destruction, and excretion). Other causes of vitamin B_{12} deficiency include inadequate proteolytic degradation of vitamin B_{12} from protein, or congenital intrinsic factor deficiency. In addition, the gastric mucosa may be unable to produce intrinsic factor under conditions such as partial gastrectomy, autoimmune destruction (e.g., Addisonian or juvenile pernicious anemia), or destruction of the gastric mucosa from caustic agents.

Pernicious anemia can result in vitamin B_{12} deficiency.[24,25] It can be caused by chronic atrophic gastritis accompanied by reduced intrinsic factor and hydrochloric acid secretion or acquired as a result of gastrectomy, pancreatic disease, or malnutrition. Pernicious anemia occurs commonly in patients with thyrotoxicosis, autoimmune thyroiditis, vitiligo, rheumatoid arthritis, or gastric cancer. Intrinsic factor and parietal cell autoantibodies may be observed in the serum of patients with pernicious anemia.

The onset of the pernicious anemia is insidious. Patients generally do not feel well for months and often complain of at least two of the following symptoms: weakness, sore tongue, and symmetric numbness or tingling in the extremities. The neurologic symptoms of vitamin B_{12} deficiency are associated with a defect in myelin synthesis and often are described as peripheral neuropathy or nonspecific complaints (e.g., tinnitus, neuritis, vertigo, headaches).

LABORATORY EVALUATION

In general, the serum vitamin B_{12} level reliably reflects vitamin B_{12} tissue stores.

Falsely low vitamin B_{12} concentrations may be observed in patients with folic acid deficiency, transcobalamin I deficiency, multiple myeloma, or pregnancy.[21] Falsely normal levels may be observed in patients with myeloproliferative, liver, or renal disease. Measuring serum methylmalonic acid and homocysteine levels may also differentiate between folate and vitamin B_{12} deficiency. Once vitamin B_{12} therapy has been instituted, serum levels of these chemicals decrease if true vitamin B_{12} deficiency is present.

The cause of vitamin B_{12} deficiency may be determined by the use of antibody testing (antiparietal cells and anti-intrinsic factor antibodies).[25,26] Patients with pernicious anemia are not able to absorb vitamin B_{12} because intrinsic factor is not available for binding. Some patients produce intrinsic factor but are still unable to absorb dietary vitamin B_{12}. Malabsorption, which occurs more commonly in the elderly, can be caused by intestinal bacteria that usurp vitamin B_{12}, achlorhydria, chronic acid suppression therapy, pancreatic insufficiency, alcohol abuse, inadequate disassociation of vitamin B_{12} from proteins, or lack of intrinsic factor receptors secondary to ileal loops, bypass, or surgical resection.[27]

PERNICIOUS ANEMIA

Signs, Symptoms, and Laboratory Findings

CASE 92-2

QUESTION 1: C.L. is a 63-year-old Scandinavian man that is seen by a private physician. C.L. has a 1-year history of weakness and emotional instability. He also complains of a painful tongue, alternating constipation and diarrhea, and a tingling sensation in both feet. Pertinent findings on physical examination include pallor, red tongue, vibratory sensory loss in the lower extremities, disorientation, muscle weakness, and ataxia.

Significant laboratory findings include the following:

Hgb, 8.7 g/dL
Hct, 27%
MCV, 115 fL
MCH, 38 pg/cell
MCHC, 340 g/L
Reticulocytes, 0.4%
Poikilocytosis and anisocytosis on the blood smear
White blood cell (WBC) count, 4,000/µL
Platelets, 100,000/µL
Serum iron, 90 mcg/dL
TIBC, 350 g/dL
Ferritin, 140 ng/mL
RBC folate, 300 ng/mL
Serum vitamin B_{12}, 90 pg/mL
Intrinsic factor antibody positive

What signs, symptoms, and laboratory findings in C.L. are typical of pernicious anemia?

C.L.'s signs and symptoms are classic for pernicious anemia. This disease occurs equally in both sexes (primarily in individuals of northern European descent), with an average onset of 60 years.[28] Pernicious anemia develops from a lack of gastric intrinsic factor production which causes vitamin B_{12} malabsorption and, ultimately, vitamin B_{12} deficiency. C.L.'s signs and symptoms of vitamin B_{12} deficiency include painful red tongue, loss of lower extremity vibratory sense, vertigo, and emotional instability. The elevated MCV suggests megaloblastic anemia.

Folate and iron are two other factors that can affect the MCV and should be evaluated during the workup of a patient for anemia. In this case, C.L.'s folate and iron levels are normal, but his serum vitamin B_{12} level is low. The presence of poikilocytosis and anisocytosis observed in the blood smear represents ineffective erythropoiesis. Other cell lineages also may be affected in the bone marrow. Erythroid hypercellularity, along with a decrease in the myeloid cells (leukocytes and platelets), increases the erythroid to myeloid ratio in C.L. The patient's low Hgb, elevated MCV, low serum vitamin B_{12} levels, and presence of intrinsic factor antibodies are compatible with the diagnosis of pernicious anemia, which is often associated with atrophic body gastritis. The Schilling test, which confirms intestinal malabsorption of vitamin B_{12}, is no longer available in the United States.[21]

Treatment

CASE 92-2, QUESTION 2: How should C.L.'s pernicious anemia be treated? How soon can a response be expected?

C.L. should receive parenteral vitamin B_{12} in a dose sufficient to provide the daily requirement of approximately 2 mcg and the amount needed to replenish tissue stores (about 2,000–5,000 mcg; average, 4,000 mcg). To replete vitamin B_{12} stores, cyanocobalamin can be given IM in accordance with various regimens as shown in Table 92-9.[29] Intramuscular or deep subcutaneous administration provides SR of vitamin B_{12} with better utilization compared with rapid IV infusion. An oral tablet or intranasal cyanocobalamin solution is also available for maintenance therapy, after the patient has normalized blood counts.

Treatment with vitamin B_{12} should completely reverse the hematologic complications of pernicious anemia.[22,23] The reticulocyte count increases within the first week of treatment and the megaloblastic anemia resolves within 6 to 8 weeks. Neurologic symptoms may worsen at first and then resolve over weeks to months. Some symptoms may never resolve completely. Because the rapid production of RBCs can increase potassium demand, serum potassium should be monitored and potassium supplementation provided as necessary. Peripheral blood counts should be obtained every 3 to 6 months to evaluate the adequacy of therapy. If maintenance therapy is discontinued, pernicious anemia will recur within years, making patient adherence vital to long-term success.

Oral Vitamin B^{12}

CASE 92-2, QUESTION 3: What factors affect the oral absorption of vitamin B_{12}? When might oral vitamin B_{12} therapy an effective alternative to parenteral therapy for C.L.?

The amount of vitamin B_{12} that can be absorbed orally from a single dose or meal ranges from 1 to 5 mcg; approximately 5 mcg of vitamin B_{12} is absorbed daily from the average American diet.[23] The percentage of vitamin B_{12} absorbed decreases with increasing doses: 50% of a 1 mcg dose and 5% of a 20 mcg dose. Overall, oral vitamin B_{12} therapy is considered safe and effective,[30] although because of lack of long-term efficacy data, oral supplementation is not routinely used in the acute treatment of vitamin B_{12} deficiency.[27] Oral therapy for pernicious anemia using high dosages of oral cyanocobalamin may be indicated in certain patients, especially those who refuse or cannot receive parenteral therapy.[27,31] Issues of nonadherence or lack of response with oral therapy places the patient at substantial risk for significant neurologic damage. Patients receiving oral vitamin B_{12} therapy should be monitored more frequently to ensure adherence to therapy.

Anemias After Gastrectomy

CASE 92-3

QUESTION 1: F.M. has just undergone a total gastrectomy for recurrent nonhealing ulcers. What form(s) of anemia would be expected to develop in a patient after gastrectomy? Should F.M. receive prophylactic vitamin B_{12}?

Partial or total gastrectomy often results in anemia, particularly pernicious anemia, because the loss of intrinsic factor impairs oral vitamin B_{12} absorption. The hematologic and neurologic abnormalities associated with vitamin B_{12} deficiency do not develop until existing vitamin B_{12} stores are depleted (about 2–3 years). Nevertheless, prophylactic vitamin B_{12} should be administered in this patient after total gastrectomy.[32] Because the vitamin B_{12} stores are not currently depleted, maintenance therapy, as discussed in Case 92-2, Question 2, should be adequate for F.M.

Table 92-9

Cyanocobalamin (Vitamin B_{12}) Supplementation Regimens for Macrocytic Anemia[29]

Patient Population	Initial Supplementation			Chronic Supplementation (lifelong)		
	Dose	**Frequency**	**Route**	**Dose**	**Frequency**	**Route**
Adults	100 mcg	Daily for 7 days, then on alternate days for 14 days, then q 3–4 days for 2–3 weeks	IM or SC	100–200 mcg	Monthly	IM or SQ
Severe Deficiency	100–1,000 mcg	Daily or every other day for 1–2 weeks	IM or SC	100–1,000 mcg	every 1–3 months	IM or SQ
				500 mcg	Weekly	Intranasal
	1,000–2,000 mcg	Daily for 1–2 weeks	Oral	1,000 mcg[a]	Daily	Oral

[a] In patients with normal gastrointestinal absorption, doses of 1–25 mcg daily are considered sufficient as a dietary supplement.

IM, intramuscular; SC, subcutaneous.

Anemias After Gastric Bypass

CASE 92-4

QUESTION 1: P.G. is a 48-year-old female scheduled to have laparoscopic Roux-en-Y gastric bypass (RYGB) surgery for morbid obesity with a body mass index (BMI) >40.

What forms of anemia would be expected to develop in P.G.?

When a RYGB procedure is performed, the stomach is decreased in size, and the small intestine is manipulated creating a gastrojejunostomy and jejunojejunostomy.[33] This results in bypassing the duodenum and proximal jejunum where iron is absorbed, resulting in iron deficiency anemia. The gastric pouch is no longer an acidic environment which impairs iron bioavailability and functioning of iron transport mechanisms. Patients are also recommended to avoid red meat which is a common dietary source of iron. An acidic environment is also needed for the bioavailability of vitamin B$_{12}$ leading to decreased absorption. The diagnosis of vitamin B$_{12}$ deficiency following bariatric surgery is rare due to the large amount stored in the body. Folate deficiency may occur from reduced dietary folate intake. The majority of folate is absorbed from the upper third of the small intestine, but may occur at any location. Iron deficiency anemia is the most common cause for anemia in bariatric surgery patients; however, other micronutrient deficiencies may also contribute.

CASE 92-4, QUESTION 2: What prophylactic strategies might P.G. employ to prevent anemia?

Following bariatric surgery, patients will need to take lifelong multivitamin and micronutrient supplementation.[34] Patients should take a high potency multivitamin with 100% of the recommended daily value for at least 75% of the nutrients. It should have a minimum of 18 mg iron, 400 mcg folic acid, selenium, and zinc.[35] Patients should be instructed to take an additional 1 to 2 tablets per day of an iron salt, ferrous sulfate, or ferrous fumarate to prevent iron deficiency anemia. In addition to a high potency multivitamin, patients should take 350 to 500 mcg/day of oral cyanocobalamin or receive 1,000 mcg injections monthly.

Folic Acid Deficiency Anemia

FOLIC ACID METABOLISM

Folate is abundant in virtually all food sources, especially fresh green vegetables, fruits, yeast, and animal protein. As a result of food fortification, the average American diet provides 50 to 2,000 mcg of folate per day; however, excessive or prolonged cooking (>15 minutes) in large quantities of water may reduce the folate contained in food.[36] Human requirements for folate vary with age and depend on the rate of metabolism and cell turnover but are generally 3 mcg/kg/day.[36] The minimal daily adult requirement of folate is 50 mcg but, because absorption from food is incomplete, a daily intake of 200 mcg is recommended. Folate requirements are increased in conditions in which the metabolic rate and rate of cellular division are increased (e.g., pregnancy, infancy, infection, malignancies, hemolytic anemia). The following are estimates of daily folate requirements based on age and growth demands: children, 80 to 400 mcg; infants, 65 mcg; pregnant or lactating women, 600 mcg.[37]

Dietary folic acid is in the polyglutamate form and must be enzymatically deconjugated in the GI tract to the monoglutamate form before it is absorbed. Once absorbed, the inactive dihydrofolate must be converted to active tetrahydrofolate (folinic acid) by dihydrofolate reductase.

In contrast to the large stores of vitamin B_{12}, the body's folate stores are relatively small (about 5–10 mg). Therefore, deficiency and subsequent megaloblastic anemia can occur within 3 to 4 months of decreased folate intake.

PREDISPOSING FACTORS

Folate deficiency is most commonly associated with alcoholism, rapid cell turnover, and dietary deficiency. In alcoholics, the daily intake of the folate contained in food may be restricted or absent. In addition, enterohepatic recirculation of folate can become impaired by the toxic effect of alcohol on hepatocytes. Folate deficiency may also develop during the third trimester of pregnancy as a result of a marginal diet and rapid fetal metabolism. Folate coenzymes are required for most metabolic pathways (Fig. 92-2). Therefore, folate deficiency will develop in any condition of rapid cellular turnover (e.g., hemolytic anemias, hemoglobinopathies, sideroblastic anemia, leukemias, lymphomas, multiple myeloma) or a diet lacking in folate (e.g., food faddism or a weight-loss diet). Folate deficiency also can occur with chronic hemodialysis, diseases that impair absorption from the small intestine (e.g., sprue, regional enteritis), extensive jejunal resections, and drugs that alter folate metabolism (e.g., trimethoprim, pyrimethamine, methotrexate, sulfasalazine, oral contraceptives, anticonvulsants).[38,39] Few patients have inborn errors of folate metabolism.[40]

The evaluation of megaloblastic anemia must be thorough because indiscriminate use of nondirected therapy can be dangerous. Large doses of folate can partially reverse hematologic abnormalities caused by vitamin B_{12} deficiency; however, folate cannot correct neurologic damage caused by vitamin B_{12} deficiency. Therefore, folate deficiency must be differentiated from vitamin B_{12} deficiency before folate therapy is initiated. Otherwise, progression of the neurologic sequelae of vitamin B_{12} deficiency can occur.

CASE 92-5

QUESTION 1: D.H. is a malnourished-appearing woman in her second trimester of pregnancy who presents to the local health clinic for her regular checkup. She is a multiparous, 26-year-old woman with a 7-year history of excessive alcohol intake and has been using cocaine frequently for 3 years. She lives with her boyfriend and her 19-month-old daughter. During both pregnancies, D.H. lost 8 to 10 pounds during the first trimester secondary to nausea, vomiting, and anorexia. Her only complaints are dyspnea on exertion, palpitations, and diarrhea.

Pertinent laboratory values include the following:

Hct, 25.5%
MCV, 112 fL
MCH, 34 pg/cell
RBC, 1.1 × 10^6/µL
Iron, 179 mcg/dL
Folate, 40 ng/mL
Serum vitamin B_{12}, 350 pg/mL (normal, 200–1,000)
Reticulocytes, 1%
Platelets, 70,000/µL
WBC count, 2,000/µL with hypersegmented polymorphonuclear neutrophils (PMN)
LDH, 425 units/L
Bilirubin, 1.2 mg/dL

D.H. is not taking any prescription medications. What factors make D.H. at risk for folate deficiency?

As with most patients who are folate deficient, D.H. has more than one risk factor. Cocaine and alcohol, together with multiparity complicated by anorexia, nausea, and vomiting, could lead to poor nutrition. Alcohol has toxic effects on the intestinal mucosa and interferes with folate utilization by the bone marrow. D.H. should be asked specifically about her dietary habits and recent weight history. She may have a folate-poor diet for financial reasons or because she is overcooking her food. Alternatively, cocaine may be causing anorexia. The nutritional intake of people who abuse alcohol and drugs is often poor. The diagnosis of folate deficiency is plausible, considering folate deficiency can develop in a matter of weeks to months.

Thymidine and DNA Synthesis (Deoxythymidine MP)
Methionine Synthetase
5-Methyl THF
DNA Synthesis
Methionine

Figure 92-2 Intracellular metabolic pathways. Vitamin B_{12} and folic acid are both necessary for nucleic acid precursors used for DNA synthesis. DHF, dihydrofolate; MP, monophosphate; TCII, transcobalamin II; THF, tetrahydrofolate.

DIAGNOSIS AND MANAGEMENT

CASE 92-5, QUESTION 2: Which laboratory values support the diagnosis of folate deficiency? How should D.H. be treated and monitored?

D.H.'s laboratory values reflect macrocytic anemia (Hct, 25.5%; MCV, 112 fL) with pancytopenia (reduced number of RBCs, WBCs, and platelets). Serum vitamin B_{12} concentrations reflect normal vitamin B_{12} stores, but folate stores are inadequate as exemplified by the low RBC folate concentration, pancytopenia, and macrocytic anemia.

Serum folate concentrations generally reflect folate balance during the past 3 weeks although one balanced meal can raise serum levels and falsely elevate body stores. Tissue folate stores are more accurately reflected by the RBC polyglutamated folate content, which is approximately 10 to 30 times the corresponding serum folate concentrations.[41] Hemolysis or vitamin B_{12} deficiency causes leakage of monoglutamated folates from cells, thereby falsely elevating serum folate levels.[42]

D.H. should be counseled regarding her nutritional and social habits. Because the estimated total body folate store is only about 5 to 10 mg, 1 mg of folic acid given daily for 2 to 3 weeks should be more than adequate to replace her storage pool of folate. Higher dosages (up to 5 mg) may be needed, however, if absorption is compromised by alcohol or other factors.[38] Once stores are replenished, D.H. should continue folate supplements throughout her pregnancy and lactation period. She should be reassessed after the course of therapy to determine response to therapy and whether the cause of the folate deficiency has been corrected. Supplementation with folic acid 1 mg/day may be required as long as risk factors are present. D.H.'s fetus is unlikely to develop folate deficiency because maternal folate is preferentially delivered to the fetus; however, sustained folate deficiency during pregnancy can cause birth defects in the newborns (see Chapter 49, Obstetric Drug Therapy).

D.H.'s response to therapy can be monitored by several different parameters. Although bone marrow aspirates are not obtained routinely, the RBC morphology should begin to revert back to normal within 24 to 48 hours after therapy is initiated, and hypersegmented neutrophils should disappear in the periphery in about 1 week. Serum chemistry and hemogram studies should begin to normalize within 10 days. The reticulocyte count should increase by day 2 to 3 and peak by day 10. Bilirubin and LDH values should normalize in 1 to 3 weeks. Finally, the anemia should be corrected in 1 to 2 months. Once anemia is corrected, 100 mcg

---

daily of folate as a nutritional supplement should be adequate for maintenance treatment (independent of the patient's pregnancy/lactation status).

SICKLE CELL ANEMIA

Pathogenesis

Sickle cell anemia is an inherited, autosomal recessive Hgb disorder characterized by a DNA substitution at the β-globin gene.[43] Hgb is a quaternary structure composed of two α-globin chains and two β-globin chains ($\alpha 2\beta 2$) in adults. During fetal development, the γ-globin is the primary β-globin expressed, forming fetal Hgb (HbF or $\alpha 2\gamma 2$). Normally, the period from birth to approximately 3 to 6 months of age is marked by the replacement of γ-globin with β-globin, giving rise to the adult form of Hgb (HbA, $\alpha 2\beta 2$).[44,45]

Sickle cell anemia results from a DNA substitution of thymidine for adenine in the glutamic acid codon, forming a B6 valine instead of glutamic acid.[45] βS represents the inheritance of the sickle β-globin gene.[46] The Hgb produced from this substitution has a more negative charge than normal HbA and in the deoxygenated state will aggregate and polymerize, forming sickled RBCs.[44,45] Sickled RBCs are more rigid and may become “lodged” when passing through the microvasculature, resulting in vascular occlusions.

In addition, the sickled RBC surface contains rearranged aminophospholipids, which augment the ability of the RBC to initiate coagulation, adhere to vascular endothelium, and activate complement. Abnormal interactions with other cell types cause hemolysis and vaso-occlusion, producing several complications such as anemia, pain, increased infections, and multi-organ damage.[44] For these reasons, much effort has been focused on neonatal diagnosis to reduce morbidity and mortality in children younger than 3 years of age.[47]

More than one inheritance pattern results in abnormal Hgb polymerization. Patients with sickle cell anemia are homozygous, inheriting a sickle gene from each parent (α2βS2), whereas patients with sickle cell trait are heterozygous and have inherited the sickle cell gene from one parent and the HbA gene from the other parent (α2βAβS). Other inheritance patterns include patients with a sickle cell gene and a hemoglobin C (HbC) gene (in which glutamic acid is substituted for lysine B6 [α2βSβC]). Patients may also inherit the sickle cell gene and the β-thalassemic gene (α2βSβSthal), in which case the clinical course is less severe than with patients diagnosed with sickle cell anemia.[48] Hematologic abnormalities are more commonly observed in patients with sickle cell anemia and less often in those with sickle cell HbC disease or sickle cell β_0-thalassemia.[44,45]

Laboratory Evaluation

In patients with sickle cell disease, the WBC and platelet counts often are elevated, but the WBC differential is normal.[44] The reticulocyte count can range from 5% to 15%, and the MCV may be elevated. If MCV values are within the normal range, iron deficiency or β_0-thalassemia must be considered. Sickled cells may be visually observed in poorly oxygenated blood of a patient with sickle cell anemia. In contrast, a patient with the sickle cell trait should have normal RBC morphology and WBC, reticulocyte, and platelet counts. Sickled cells are rarely observed. In patients with sickle cell β_0-thalassemia, hematologic abnormalities vary depending on the amount of HbA present. This form may be difficult to distinguish from sickle cell anemia; RBC microcytosis may be the only differentiating parameter.[44]

Clinical Course and Management

Part of efforts to improve outcomes in this population include routine screening for sickle cell anemia or sickle cell trait in newborns in the United States. Therefore, most patients are diagnosed during their first year of life. Families carrying sickle cell trait or disease are referred for genetic counseling. Patients with sickle cell disease are referred to a hematologist and multidisciplinary team for medical management.

Patients carrying the sickle cell trait experience milder symptoms than those with sickle cell anemia. The kidney is commonly affected by microinfarction, which occurs in the renal medulla and impairs the kidney’s ability to concentrate urine. During pregnancy, an increased frequency of urinary tract infections and hematuria is seen. However, vaso-occlusive events are uncommon and are usually caused by hypoxic conditions.

Treatment of sickle cell anemia is largely directed toward prophylaxis against infections and supportive management of vaso-occlusive crises. The clinical course among patients with sickle cell disease is variable and difficult to predict. Some patients experience a multitude of health problems. Organs such as the kidneys, retina, spleen, and bones are frequent sites of vaso-occlusive events because these sites have a relatively low pH and oxygen tension. Cardiac, pulmonary, neurologic, hepatobiliary, obstetric/gynecologic, ocular, dermatologic, or orthopedic complications can also occur. The management of these complications is organ specific and primarily aimed at supportive interventions.

Sickle cell HbC disease is usually associated with few clinical complications. These patients may have normal physical examination findings with only splenomegaly. Patients are at risk for bacterial infections and, because of elevated Hgb levels, they may experience ocular, orthopedic, and pulmonary vaso-occlusive events.[44,48]

INFECTIONS

CASE 92-6

QUESTION 1: B.C. is a 4-month-old girl who has recently been diagnosed with sickle cell anemia (both parents positive for sickle cell trait). Her older sibling is positive for sickle cell trait but is asymptomatic.

How does B.C.’s diagnosis affect her risk of infections?

B.C. is at an increased risk for infections because sickle cell anemia causes defects in splenic function, complement activation, granulocyte function, and B-cell immunity, as well as micronutrient deficiencies.[49] Impaired splenic function increases B.C.’s risk for infection from polysaccharide-encapsulated bacteria such as Streptococcus pneumoniae, Haemophilus influenzae, Neisseria meningitidis, and Salmonella typhimurium. These infections occur most frequently in early childhood, although B.C. will have a lifelong increased risk of infection. Pneumonia caused by S. pneumoniae, mycoplasma, or viruses can worsen hypoxia, causing progression to vaso-occlusion and acute chest syndrome (discussed in more depth below). Pulmonary complications from pneumonia or vascular occlusion can also lead to right-sided heart failure. Other infectious conditions such as osteomyelitis from Staphylococcus aureus or S. typhimurium or urinary tract infections caused by

Escherichia coli are common complications in patients with sickle cell anemia.[44,46]

CASE 92-6, QUESTION 2: What preventive measures should be taken to prevent infections in B.C.?

Patients with sickle cell anemia should use general preventive measures, such as frequent hand-washing, avoiding sick contacts,

---

and thoroughly cooking foods that may carry Salmonella (e.g., chicken or eggs).[49] Children should be closely monitored for symptoms and antibiotic therapy should be instituted at the earliest sign of infection. Prophylactic administration of penicillin has significantly reduced morbidity and mortality from pneumonia in children younger than 3 years of age[50] and is recommended to be continued through age 5.[46] Patients such as B.C. should receive 62.5 mg twice daily during the first year of life, increased to 125 mg twice daily for ages 1 through 3, then 250 mg twice daily until the age of 5. The US guidelines recommend discontinuing penicillin prophylaxis at age 5 unless the child has undergone splenectomy or has had an invasive pneumococcal infection.[51]

Vaccines that are recommended for patients with homozygous sickle cell include all standard pediatric and adult vaccines. B.C. also should receive the pneumococcal 23-valent polysaccharide vaccine at 2 and 5 years of age with a booster every 10 years throughout her life.[47] Because patients with sickle cell typically respond poorly, only 50% of patients will be protected by vaccination. Therefore, there is a continued need for penicillin prophylaxis in young children.[52]

CASE 92-6, QUESTION 3: B.C. is now 3 years old and presents with pallor and significantly decreased activity. Her mother notes that some of B.C.'s daycare classmates have been experiencing a mild viral illness and rash. Her pediatrician obtains a CBC with the following results:

Hgb, 6.2 g/dL
Hct, 18.1%
Platelets, 97,000/μL
Reticulocyte count, 0.5%
WBC count, 6,000/μL

What is a potential cause of B.C.'s symptoms and how should they be managed?

Human parvovirus (HPV) B19 is a common cause of transient RBC aplasia, with up to 67% of infections resulting in a hematologic change typical of aplasia.[53] It is a common, highly contagious childhood infection with more than 70% of adults testing seropositive.[49] Nearly 70% of all homozygous sickle cell patients are HPV B19 seropositive by 20 years of age.[54] In normal individuals, the infection is asymptomatic or presents as mild flu-like symptoms with or without a generalized maculopapular rash. The virus also infects RBC progenitor cells in the bone marrow, causing a temporary 7- to 10-day cessation of erythropoiesis in 65% to 80% of infected individuals. In normal individuals, RBC lifespan is 120 days and this does not typically produce symptoms. Patients with sickle cell anemia have an RBC lifespan of 5 to 15 days, so the temporary break in erythropoiesis leads to a severe anemia. Thrombocytopenia has been noted in approximately one-fourth of those infected with less than 20% of patients experiencing neutropenia. Although most children recover within 2 weeks, the majority will require blood transfusions to manage anemia.

Vaso-occlusive Complications

CASE 92-7

QUESTION 1: J.T. is an 18-year-old man with sickle cell anemia who presented to the emergency department with rapid onset of abdominal pain and shortness of breath.

During early childhood, he experienced several episodes of acute pain, swelling of the hands and feet, and jaundice. Three years before this admission, J.T. required a left hip replacement due to osteonecrosis caused by sickle cell anemia. Recently, frequent blood transfusions have reduced the frequency of sickling crises.

Physical examination reveals J.T. as a thin black man in acute distress and with scleral icterus. He has a pulse of 118 beats/minute, a respiratory rate of 17 breaths/minute, and a temperature of 98.8°F. His lungs are clear. Splenomegaly is noted, and a chest radiograph reveals only cardiomegaly.

A CBC is obtained. Notable results include the following:

Hgb, 5.9 g/dL
Hct, 27%
WBC count, 5,000/μL
Platelets, 335,000/μL
Reticulocyte count, 1%
Bilirubin, 5.8 mg/dL
Serum creatinine, 3.1 mg/dL
Blood urea nitrogen, 54 mg/dL

The peripheral blood smear shows target cells with an occasional sickled cell. What signs and symptoms are consistent with sickle cell anemia? What is J.T.'s current complication?

Vaso-occlusive crisis, or "sickle cell crisis," is caused by severe pain and organ damage. These may be precipitated by many factors including hypoxia, dehydration, infection, and pregnancy.[55] Based on the presence of splenomegaly and anemia with target and sickled cells, J.T. currently is presenting with an acute splenic sequestration crisis. Acute splenic sequestration is caused by the trapping of RBCs within the spleen. This causes splenomegaly and progressive anemia. The low reticulocyte count is consistent with acute sequestration because a reticulocyte response would be expected if the anemia had developed in recent days. J.T.'s inadequate reticulocyte response may reflect rapid progression of the anemia, HPV B19 infection, or a blunted EPO response secondary to compromised renal dysfunction.

CASE 92-7, QUESTION 2: How should J.T. be treated?

J.T.'s signs and symptoms are sufficiently serious to justify transfusion therapy.[51] In addition, J.T. should be adequately hydrated, considering his elevated serum creatinine and blood urea nitrogen. Because patients with sickle cell anemia often lose the ability to concentrate urine, they may become dehydrated, which further contributes to cell sickling. The pain associated with a crisis typically lasts at least 2 to 6 days and should be managed with analgesics including parenteral opioids for severe pain. Pain control should be aggressively instituted for J.T.'s comfort and should be continued for a few days after hospital discharge (also see Chapter 55, Pain Management). It is important not to withhold opioids because of a fear of addiction.[55]

Splenectomy may be indicated in instances of severe splenomegaly, repeated infarction, or pain in adults and it is indicated when crises occur in children. Those patients with sickle cell anemia who are bedridden should be placed on chronic heparin therapy to prevent vascular occlusions and deep vein thrombosis.

CASE 92-7, QUESTION 3: J.T. presents to the emergency department 3 months later with complaints of fever, cough, and severe throbbing pain in his chest and abdomen beginning 2 days prior. This is his third admission within the last year. Notable laboratory results include the following:

Hgb, 6.6 g/dL
Hct, 18.9%

Platelets, 218,000/μL
WBC, 19,700/μL
Bilirubin, 4.7 mg/dL
Serum creatinine, 1.1 mg/dL

His chest radiograph shows diffuse interstitial infiltrates in both lung fields. His vital signs are as follows: blood pressure, 98/53 mm Hg; heart rate, 102 beats/minute; respiratory rate, 23 breaths/minute; temperature, 101.4°F; and oxygen saturation, 93%. What complication of sickle cell disease is J.T. experiencing and how should he be treated for this condition?

J.T. is experiencing acute chest syndrome, a leading cause of morbidity and mortality in patients with sickle cell disease. The diagnosis of acute chest syndrome is determined by new pulmonary infiltrates on chest radiograph with one or more of the following: fever, cough, worsening anemia, and pleuritic or nonpleuritic chest pain. Patients may also experience shortness of breath, rales, hypoxia, and wheezing (more commonly in children).[51] Causes of acute chest syndrome include pulmonary fat embolism, pulmonary infarction, and infection.[3] Commonly implicated organisms include Chlamydia pneumoniae, Mycoplasma pneumoniae, S. pneumoniae, Haemophilus influenzae, and various viruses.

The primary goal of treatment is to prevent progression to acute respiratory failure; therefore, treatment should involve pain management, hydration, oxygen supplementation, incentive spirometry, antibiotics, and, potentially, transfusion.[51] Optimal pain control and incentive spirometry are important to prevent hypoventilation and atelectasis, as well as to increase patient comfort. Oxygen should be administered nasally to patients who are moderately hypoxemic (O_2 saturation, 92%–95%; Pao_2, 70–80 mm Hg), as J.T. is. Patients who are febrile or severely ill should receive IV broad-spectrum antibiotics as it is difficult to exclude bacterial causes of acute chest syndrome. Empiric antibiotic therapy should take into account the commonly implicated organisms described above.

Transfusions are used to increase the oxygen affinity of blood and are indicated in patients with hypoxemia or whose clinical status is deteriorating and with a hemoglobin >1.0 g/dL less than baseline. J.T. should be monitored closely for deteriorating respiratory function and should receive transfusions if his clinical status does not improve.

TREATMENT FOR FREQUENT VASO-OCCLUSIVE CRISES

CASE 92-7, QUESTION 4: What preventive therapies exist for J.T. that will reduce occurrences of vaso-occlusive crises?

Hemoglobin F has a protective effect against Hgb polymerization. Investigators have observed that patients with HbF levels greater than 20% experience a relatively mild or benign course with fewer vaso-occlusive crises.[55] Hydroxyurea has been found to increase HbF synthesis which may decrease RBC sickling and the occurrence of disease-related complications.[56–58] Hydroxyurea is used prophylactically in patients with recurrent moderate-to-severe vaso-occlusive crises but not in acute treatment. The use of hydroxyurea in the sickle cell population should be carefully weighed for risk versus benefit, because it is a cytotoxic agent associated with bone marrow suppression. The US guidelines recommend hydroxyurea for adult patients who have three or more sickle cell-associated moderate-to-severe pain crises in a 12-month period.[51] Patients taking hydroxyurea should have bone marrow studies performed before therapy and periodically during therapy. Other adverse effects of hydroxyurea include GI effects (nausea, vomiting, diarrhea), dermatologic effects (maculopapular rash, pruritus), and potential risk of developing a secondary neoplasm (leukemia) with prolonged use. The treatment dose of hydroxyurea for sickle cell anemia is 15 to 35 mg/kg/day. Goals of therapy include improvement in pain and well-being, increase in HbF, increased Hgb (if severely anemic), and maintenance of acceptable platelet and granulocyte counts. After initiation of therapy, blood counts should be monitored closely and the dose adjusted based on efficacy and tolerability. Several clinical trials evaluating hydroxyurea show improvement in the clinical course of patients with sickle cell anemia.[57,59] Other areas of potential promise for the treatment of sickle cell anemia include bone marrow transplantation and gene therapy.[60,61]

IRON CHELATION THERAPY

CASE 92-7, QUESTION 5: Despite optimal treatment with hydroxyurea, J.T. continues to experience exacerbations of his sickle cell disease requiring blood transfusions. J.T. estimates he has required six such transfusions in the last 2 years and at least 25 units of blood in his lifetime. During a visit with his hematologist, J.T.'s serum ferritin is noted to be 1,050 mcg/L. What potential adverse effect of treatment is the hematologist's concern? What other tests may be performed to detect this?

Patients requiring chronic transfusions of PRBCs are at an increased risk for iron toxicity due to iron overload.[62] Normally, plasma iron binds with transferrin; however, if transferrin becomes saturated, patients will have higher levels of toxic nontransferrin-bound iron. As nontransferrin-bound iron increases, it deposits in other organs, most frequently the liver. Therefore, nontransferrin-bound iron produces free radicals, causing tissue damage and fibrosis.

Patients with sickle cell disease should be monitored for iron overload.[51] Obtaining a serum ferritin level is the most commonly used method of screening for iron overload, although the accuracy of this test is affected by inflammatory processes. Thus, serial serum ferritin values should be obtained when patients are not experiencing an acute crisis (i.e., steady-state values). More specific tests such as magnetic resonance imaging measure iron levels in organs such as the heart, liver, pancreas, and spleen although may not be routinely used because of cost.[62] The gold standard for assessing iron overload is liver iron concentration by biopsy, although this is an invasive procedure that should be performed by specialists.

CASE 92-7, QUESTION 6: J.T. returns for continued assessment of iron overload. His repeat serum ferritin levels are 1,357 mcg/L and 1,500 mcg/L (3 months apart). Liver iron concentration is 7.8 mg/g dry weight. Does J.T. meet the criteria to receive iron chelation therapy? What options are available?

J.T. meets criteria for iron chelation therapy because of his steady-state serum ferritin levels being consistently more than 1,000 mcg/L and his liver iron concentration being greater than 7 mg/g dry weight.[51] Other considerations for a patient to receive iron chelation therapy include transfusion of approximately 100 mL/kg of PRBCs, or 20 units for a 40-kg or more patient.

There are three iron chelators currently approved for use in patients with sickle cell disease; their dosing and adverse effects are summarized in Table 92-10. These agents work by binding free iron present in circulation and tissues. The iron is then excreted in the urine and bile.

Deferoxamine (DFO) is the oldest agent and has the most clinical experience. Deferoxamine and deferasirox have been studied in patients with sickle cell disease who are as young as 2 years old; deferiprone is not approved for use in children. Because of its short half-life, DFO must be administered daily via continuous IV or subcutaneous infusion for 5 days. Deferasirox has a longer half-life, allowing for once-daily oral administration and enhanced patient convenience and adherence. A study of 195 patients with sickle cell disease observed similar reductions in iron levels between patients receiving DFO and patients receiving deferasirox at comparable doses.[63] Additionally, more patients in the deferasirox group reported their treatment was convenient.[62] Deferiprone has predominantly been studied in patients with transfusional iron overload with inadequate response to other iron chelating therapies although it has been shown to be similar to deferasirox in patients with sickle cell anemia.[64] Deferoxamine is associated with more dose-dependent oculotoxicity and audiotoxicity, although both agents may cause this.[65,66] Deferasirox has been associated with more nephrotoxicity, hepatotoxicity, and cytopenias. Either DFO or deferasirox is appropriate for J.T. at this time.

Table 92-10

FDA-Approved Iron Chelation Therapies

Medication	Dose	Frequency	Route	Common/Serious Adverse Effects	Notes
Deferoxamine (DFO)	25–50 mg/kg/day, titrate to effect (Maximal dose 40 mg/kg for children)	Daily, Monday–Friday	SC for 8–12 hours	Common: headache, upper respiratory tract infection, abdominal pain, nausea, vomiting, pyrexia, pain, arthralgia, cough, nasopharyngitis, constipation, chest pain, injection site reactions, muscle spasms, viral infection Serious: audiotoxicity, hepatotoxicity, nephrotoxicity, ocular toxicity, hypotension, anaphylaxis, respiratory distress syndrome, growth retardation	Requires a syringe pump or balloon infuser; Rotate sites to prevent scarring
Deferasirox	Exjade: 20 mg/kg, titrate to effect Jadenu: 14 mg/kg, titrate to effect	Once daily	Exjade: oral drink Jadenu: oral tablet	Common: headache, abdominal pain, nausea, pyrexia, vomiting, diarrhea, back pain, upper respiratory tract infection, arthralgia, pain, cough, nasopharyngitis, rash, constipation, chest pain Serious: nephrotoxicity, cytopenias, hepatic failure, GI hemorrhage, anaphylaxis, ocular disturbances	Exjade should be dissolved in juice for administration
Deferiprone	75 mg/kg/day	3 times	Oral tablet	Common: chromaturia,	Urine may be

	(divided into 3 doses of 25 mg/kg), titrate to effect (max dose 99 mg/kg/day)	daily		nausea, vomiting, abdominal pain, ALT increased, arthralgia, neutropenia Serious: agranulocytosis/neutropenia, hepatotoxicity, zinc deficiency	discolored red-brown. Pregnancy category D

FDA, Food and Drug Administration; GI, gastrointestinal; SC, subcutaneously.

J.T. should also receive appropriate monitoring consisting of serial serum ferritin levels and annual audiology and ophthalmology assessments. Some centers obtain a liver biopsy every 2 years during treatment to assess efficacy.[51] Patients receiving deferasirox should have serum creatinine monitored weekly for the first month after initiation or a dose alteration and monthly thereafter.[51] Monthly monitoring for proteinuria and assessment of liver function tests should also be initiated for patients receiving deferasirox.

Other Complications of Sickle Cell Disease

NEUROLOGIC COMPLICATIONS

Neurologic complications are age dependent. Stroke most commonly occurs in the first decade of life, whereas intracerebral hemorrhage is a complication associated with adulthood. Primary prevention of stroke with RBC transfusions targeted to maintain HbS level less than 30% reduces the incidence of stroke in high-risk patients by 92%.[67] If a stroke occurs, approximately 50% of patients experience recurrent strokes within 3 years unless they are treated by chronic RBC transfusion therapy.[45] A concern with RBC transfusion therapy is iron overload. Conflicting evidence exists regarding the benefit of chronic hydroxyurea plus phlebotomy (removal of blood to reduce iron burden) as an alternative option to prevent secondary stroke.[68,69]

RENAL AND GENITAL COMPLICATIONS

Renal and genital complications are common in sickle cell disease because the environment (hypoxic, acidotic, and hypertonic) predisposes the renal medulla or corpus cavernosum to infarction. As a result, patients might experience reduced potassium excretion, hyperuricemia, hematuria, hyposthenuria, and renal failure. Patients with renal disease generally have inappropriately low levels of EPO as well. Men experiencing occlusion of the corpus cavernosum can experience acute or chronic priapism. Conservative management includes IV fluid administration and pain control. Refractory cases may require surgery.[44,46]

MICROINFARCTIONS

Microinfarctions often produce ophthalmic, hepatic, orthopedic, and obstetric/gynecologic complications as well. Patients with sickle cell anemia may require screening to detect these complications.[51]

ANEMIA OF INFLAMMATION

Anemia of inflammation (AI), also known as anemia of chronic disease, refers to a mild-to-moderate anemia that results from decreased RBC survival and production and generally occurs over months to years.[70] It has been associated with a number of disorders (e.g., autoimmune disorders, acute and chronic infections, chronic kidney disease, and malignancy).[71] Because of the common occurrence of such conditions, AI is encountered frequently and has been estimated to be the second most common anemia after iron deficiency. Most often, AI is a normochromic, normocytic anemia, although RBCs may be hypochromic and microcytic in less than a quarter of patients.[72] A prominent feature of AI is the altered availability of iron which is not reliably reflected in iron indices due to an increase of hepcidin, a hormone that regulates iron metabolism.[73] Additionally, the EPO response may be inappropriate for the degree of anemia.[74]

The pathogenesis of AI is not well understood. It appears the production of inflammatory cytokines such as interferon-γ, tumor necrosis factor-α, IL-6, and IL-1 leads to either activation of macrophages that consume and destroy erythrocytes or the suppression of erythropoiesis by inhibition of RBC precursors, such as BFUe.[75] In response to inflammation, elevated levels of IL-6 upregulate hepcidin production through the JAK-STAT pathway, inhibiting the release of iron stores to the plasma. This high concentration leads to hypoferremia (functional iron deficiency) and blunted erythrocyte production.[73] Hepcidin can further alter iron hemostasis by decreasing duodenal iron absorption.[72] A review of iron studies is important to distinguish AI from iron deficiency anemia. In AI, serum iron, transferrin saturation, and TIBC are low with an increased serum ferritin. Conversely, in iron deficiency anemia, serum iron, transferrin saturation, and serum ferritin are low with an increased TIBC. However, it is important to recognize that both forms of anemia may be seen concurrently in patients with AI.

Management of mild-to-moderate AI usually focuses on the underlying disease process. Anemia of inflammation is not usually progressive or life threatening, although it generally affects a patient's quality of life. Patients may require blood transfusions for symptomatic anemia which are associated with risks such as hepatitis, viral infections, iron overload, treatment-related acute lung injury, and immunogenic reactions. Unless a concurrent deficiency of vitamin B_{12} or folate exists, administration of vitamin supplements for AI is not of value. Iron supplementation may be warranted in patients with a functional or absolute iron deficiency anemia. Erythropoiesis-stimulating agents (ESAs) have been used successfully to treat AI in patients with rheumatoid arthritis, acquired immunodeficiency syndrome (AIDS), malignancy, and chronic kidney disease; however, medication costs and increased safety risks can be significant and risk versus benefits should be assessed when determining treatment.[72,74]

Erythropoietic Therapy

Erythropoietic therapy is indicated for use in anemia associated with chronic kidney disease, drug-induced anemia (myelosuppressive chemotherapy and zidovudine therapy), and autologous blood transfusions for elective noncardiac, nonvascular surgery.[76–78] Response to ESAs is dependent on both dose and the underlying cause of anemia and may take days to weeks to be seen. Currently, there are two ESAs, epoetin alfa (Procrit, Epogen) and darbepoetin alfa (Aranesp), approved for use in the United States. Darbepoetin differs from epoetin alfa by the addition of two carbohydrate chains. The significance of the additional carbohydrate chains is an increased sialic acid content resulting in decreased clearance and a serum half-life 3 times longer than that of epoetin alfa. These kinetic differences allow darbepoetin alfa to be administered less frequently. Table 92-11 illustrates current therapeutic uses of epoetin alfa and darbepoetin alfa. Lack of response to erythropoietic therapy (ESA hyporesponsiveness) in all patient populations is most commonly associated with iron deficiency.

Although some studies assessing the use of ESAs in the treatment of chronic kidney disease and chemotherapy-induced anemia (CIA) have shown benefit (i.e., decreased RBC transfusions), there is also evidence that use increases the risk for cardiovascular events, stroke, thrombosis, shortened overall survival, and/or increased the risk of tumor progression or recurrence in the respective patient populations.[79,80] In 2011, the FDA mandated a Risk Evaluation and Mitigation Strategy (REMS) program based on studies that identified safety concerns with the use of epoetin alpha and darbepoetin alpha. Recently the FDA performed an evaluation of the ESA REMS requirements and found that the requirements had minimal impact on ESA utilization beyond that of CMS coverage determinations and other FDA regulatory actions. As a result, in 2017, the FDA determined that it is no longer necessary to require the ESA REMS requirements and the risk and benefits of the medications can be communicated by the current product prescribing information. Healthcare providers are encouraged to discuss the risks and benefits of using ESAs with each patient prior to initiating use.

Table 92-11

Therapeutic Uses and Regimens for Recombinant Human Erythropoietin

(rhEPO)[a]

Anemia Pathogenesis	Epoetin Alfa		Darbepoetin Alfa	
	Dose (units/kg)	Frequency	Dose (mcg/kg)	Frequency
Zidovudine-induced	100	3 ×/week	—	—
Chemotherapy-induced	150 or 40,000 units (total dose)	3 ×/week or once a week, respectively	2.25 or 500 mcg (total dose)	Once a week or once every 3 weeks, respectively
Chronic kidney disease	50–100	3 ×/week	On dialysis 0.45 or 0.75 Not on dialysis 0.45	Once a week or once every 2 weeks, respectively Once every 4 weeks

[a] Adult dosing.

Renal Insufficiency-Related Anemia

The cause of renal insufficiency-related anemia is complex but involves reduced EPO production and a shortened RBC life span. Repeated transfusions are a possible treatment but can lead to complications and should be avoided unless rapid Hgb correction is needed. Because EPO is secreted in the kidney in response to anoxia and is responsible for normal differentiation of RBCs from other stem cells, erythropoietic therapy is used to treat anemia in patients with renal failure who are undergoing hemodialysis.[79,81] A dose-dependent rise in Hct is observed in patients with end-stage renal disease at approved doses of epoetin alfa or darbepoetin alfa (See Table 92-11). Targeting higher concentrations of Hgb (>13 g/dL) is associated with increased mortality and adverse effects. A FDA mandated black-box warning for these drugs states to individualize treatment to maintain use of the lowest dose of an ESA necessary to decrease the need for transfusion.[76–78] This target Hgb differs from the current kidney disease guidelines.[79,82] Refer to Chapter 28, Chronic Kidney Disease, for further information on treatment target goals as well as the appropriate use of ESAs and IV iron in patients with renal insufficiency-related anemia.

Malignancy-Related Anemia

CASE 92-8

QUESTION 1: P.M is a 62-year-old woman diagnosed with Stage IV ovarian cancer. She is being seen for her fourth cycle of chemotherapy with carboplatin and paclitaxel. She reports shortness of breath and fatigue when she walks up stairs but otherwise has a good performance status. Her CBC indicates the following:

Hgb, 9.7 g/dL
Hct, 29%
MCV, 90 mcm^3
Reticulocytes, 100 × 10^3/mcL

The peripheral smear shows normochromic and normocytic RBCs and iron studies are within normal limits. What is the most likely cause of P.M.'s anemia? What is the appropriate treatment?

P.M. appears to have malignancy-related anemia, which can be characterized as AI or CIA. Anemia is common in cancer occurring in up to 30% to 90% of patients.[83] The etiology of anemia in cancer patients is frequently complex and a conglomeration of various attributing factors such as comorbidities, malignancy, blood loss, nutritional deficiencies, and treatment with radiation and/or chemotherapy.[84] Chemotherapy-induced anemia is the result of hematopoietic impairment affecting RBC production and nephrotoxic effects of chemotherapy agents, such a platinum-containing agents, decreasing erythropoietin production.[80] It is generally normocytic and normochromic and develops over the course of treatment.[85] As with P.M., the CIA is often classified as mild to moderate and patients present as asymptomatic or mildly symptomatic (weakness, decreased exercise tolerance).[86] Factors that can influence the incidence of malignancy-related anemia in patients with cancer are the type of malignancy and the stage and duration of disease; the type, schedule, and intensity of treatment; and history of prior myelosuppressive chemotherapy or radiation. Cancer patients receiving chemotherapy should be routinely screened for CIA with a CBC. As per the NCCN Clinical Practice Guidelines in Oncology (NCCN Guidelines), evaluation for CIA should begin at an Hgb ≤11 g/dL. Additional tests including a peripheral blood smear and reticulocyte count as well as other potential causes of anemia should be performed.

The recommended treatment for CIA is comprised of transfusion or use of ESAs with or without iron supplementation.[80] Therapy should be directed to the underlying disease, if possible. When considering treatment options, transfusion with packed red blood cells (PRBC) should be used when rapid correction of Hgb is warranted with an expected 1 g/dL increase in Hgb and 3% increase in Hct with a single unit of PRBC. The use of transfusion for chronic management is associated with known risks, notably an increased risk of thromboembolic events in patients with cancer.[87] Conflicting data exist regarding the effect of transfusion on mortality.[80] ESAs with or without iron supplementation should be considered for long-term management of anemia in a patient with cancer because it has been shown to reduce transfusion requirements. Large, randomized, multicenter trials have failed to show a clinical benefit to using ESAs in anemia that is not chemotherapy-induced. The reported increased risk of mortality and tumor progression in clinical trials of anemic patients with head and neck, breast, nonsmall cell lung, lymphoid, and cervical cancers receiving ESAs resulted in a black-box warning being added to all ESA product information to advise about these and other increases in serious adverse events.[88] ESAs are recommended for anemic patients with cancer who are receiving myelosuppressive chemotherapy and the intent of treatment is not curative, with the possible exception of small cell lung cancer as there are no clinical trials reporting a deleterious impact on survival. As recommended by the FDA, treatment with an ESA should not be initiated until the Hgb is less than 10 g/dL and there is an additional 2 months of chemotherapy planned. The lowest dose needed to avoid RBC transfusion should be given, and use should be discontinued at the end of chemotherapy treatment.[76–78] Although response rates to ESAs have been reported upwards of 70% to 80% in clinical trials, not all patients will respond to treatment.[89] The most common cause of nonresponse to erythropoietic therapy is absolute or functional iron deficiency. Iron studies should be evaluated before and during therapy with supplementation given if needed. Oral or intravenous iron may be used for supplementation but data from clinical trials show intravenous iron is superior when given with an ESA.[80]

In P.M.'s case, the clinician may choose from a number of anemia management options. For example, the current course of chemotherapy can be delayed to allow for hematologic recovery and resolution of anemia symptoms. Alternatively, an RBC transfusion can be given to relieve her symptoms and allow her to better tolerate chemotherapy. Erythropoietic therapy with epoetin alfa or darbepoetin alfa also should be considered because the patient has metastatic disease (not curative) and will continue on chemotherapy until disease progression. Treatment with epoetin alfa or darbepoetin alfa increases Hgb and decreases the need for blood transfusions. If treatment with epoetin alfa is desired for P.M., therapy can be administered at an initial dose of 150 units/kg subcutaneously 3 times a week or 40,000 units once a weekly.[77,78] Alternative dosing regimens, 80,000 units every 2 weeks or 120,000 units every 3 weeks, have proved to be safe and effective in terms of hematopoietic and transfusion effects.[80,90] Darbepoetin alfa is also a treatment option for P.M. Initial dosing of darbepoetin alfa is 2.25 mcg/kg subcutaneously once a week or 500 mcg every 3 weeks.[76,91] Alternative dosing regimens of darbepoetin alfa 100 mcg once weekly, 200 mcg every 2 weeks and 300 mcg every 3 weeks have reported similar beneficial effects seen with epoetin alfa.[93–94] Response of ESAs is monitored by measuring Hgb weekly until stabilization. During this time, the dose should be titrated to the lowest dose needed to avoid transfusion. A minimum of 2 weeks is required before an increase in RBCs is seen. A reduction in dose (25% for epoetin alfa and 40% for darbepoetin alfa) is required if there is a greater than 1 g/dL rise in the Hgb in any 2 week period or the Hgb reaches a level to avoid transfusion. If no response (less than 1 g/dL rise in Hgb and Hgb remains below 10 g/dL) is seen in 4 weeks with epoetin alfa or 6 weeks with darbepoetin alfa, a dose increase should be considered. Common dose escalation schedules for epoetin alfa include escalating to 300 units/kg 3 times a week if initially treated with 150 units/kg 3 times a week or 60,000 units once a week if initially on 40,000 units once a week. Dose escalation for darbepoetin would consist of an increase to 4.5 mcg/kg once weekly if prior treatment was 2.25 mcg/kg weekly. The need for iron supplementation should also be considered at this time. Response should again be assessed at week 8 or 9 and appropriate dose reductions made based on Hgb level or transfusion avoidance. If no Hgb response is noted after 8 or 9 weeks of treatment or transfusions are still required, the drug should be discontinued.[76–78]

Human Immunodeficiency Virus (HIV)-Related Anemia

Anemia is a common finding in patients with HIV and correlates with the severity of disease as well as clinical outcomes.[95] In this patient population, anemia that has been identified is an independent prognostic factor for increased morbidity and mortality.[96] It has also been shown to be a marker of treatment failure in patients who do not achieve viral suppression and thus should be monitored as part of treatment.[97] Several factors may lead to the development of anemia in HIV patients including infections, malignancies, the presence of genetic disorders of hemoglobin, nutritional deficiencies, and the use of combination antiretroviral therapy (cART). Examples of infections includes bacteria (Mycobacterium avium complex disease), fungus (Histoplasmosis), and viruses (CMV, herpes simplex viruses type 1 and 2, and HPV B19). The use of myelosuppressive cART drugs such as zidovudine, zalcitabine, didanosine, lamivudine, and other medications often used to treat AIDS-associated illnesses (e.g., bone marrow suppressive chemotherapy, ganciclovir, trimethoprim–sulfamethoxazole, dapsone) also contributes. Additionally conditions like malignancies, Kaposi’s sarcoma, and lymphoma, all of which impair normal bone marrow function, predispose these patients to anemia.[98] Vitamin B_{12} deficiency is a contributing cause to anemia in up to a third of patients[97] and is correlated with progression to AIDS.[99] Vitamin B_{12} malabsorption can result from HIV-infected mononuclear cells within the ileum and altered gastric mucosal functioning caused by infection.[100] Alterations in the utilization of vitamin B_{12} and folate[101] can place a patient at risk for hematologic toxicity from drugs such as zidovudine and trimethoprim. More recently, evidence suggests the actual virus may play a role in the pathophysiology resulting in decreased erythropoiesis and erythropoietic response.[95] Common features of HIV-related anemia are comprised of a decreased reticulocyte count, morphologically normochromic and normocytic RBCs, adequate iron stores, and impaired response to erythropoietin.[95]

Treatment for HIV-related anemia consists of erythropoietic therapy or removal of the offending drug, if possible. Erythropoietic therapy has demonstrated increases in Hgb and quality of life in HIV-infected adult patients, regardless of drug therapy, CD4$^+$ count, or viral load.[100] While no longer first-line treatment for HIV in the United States, zidovudine is still used in pregnant women and children as well as in developing countries. Its use is associated with the development of cytopenias, primarily anemia, that occur within 3 to 6 months of beginning treatment.[102] Clinical studies show patients taking zidovudine who have baseline erythropoietin levels less than 500 units/L experience a significant reduction in transfusion requirements.[103] Epoetin alfa therapy may be initiated in patients with zidovudine-induced anemia at 100 units/kg 3 times weekly. RBC indices should be closely monitored. If the Hgb exceeds 12 g/dL, then the dose should be held until it declines to less than 11 g/dL. At that time a dose reduction of 25% or to the lowest dose necessary to prevent RBC transfusion is recommended. If a patient has no response after 8 weeks of therapy, the dose should be increased by 50 to 100 units/kg 3 times weekly at 4- to 8-week intervals or increased to 300 units/kg 3 times weekly. If no response is seen at a dose of 300 units/kg for 8 weeks, it is unlikely that the patient will benefit from further therapy and the drug should be discontinued.[76–78] Alternative once-weekly dosing with epoetin alfa has been evaluated at starting doses of 40,000 units.[104] The use of darbepoetin alfa has been assessed in HIV patients receiving hemodialysis and is as safe and effective as epoetin alfa for treating anemia.[105]

Neoplastic Disorders and Their Treatment: General Principles

Jaime E. Anderson, Andrea S. Dickens, and Katherine Tipton Patel

CORE PRINCIPLES	CHAPTER CASES
① Cancer is a group of diseases characterized by uncontrolled growth and spread of abnormal cells. Tumor metastases to distant sites generally have a greater effect than the primary tumor on the frequency of complications and the patient's quality of life and mortality.	**Case 93-1 (Question 1)**
② Avoiding known risk factors may prevent cancer. Cancer may also be prevented by appropriate use of vaccines and chemoprevention in selected groups of high-risk patients.	**Case 93-2 (Question 1)**
③ The histologic diagnosis of a tumor is the most important determinant of how a malignancy will be treated. The stage of cancer and the diagnosis influence the treatment and prognosis. As part of staging, diagnostic imaging facilitates identification of disease metastases.	**Case 93-3 (Question 1)**
④ The initial signs and symptoms of malignant disease are variable and depend on histology, location, and tumor size. This may influence treatment options if they affect performance status, which is a measure of a patient's functional capacity.	**Case 93-4 (Question 1)**
⑤ Cancer is predominately treated with three modalities: surgery, radiation, and systemic therapy. The goal of therapy should always be to cure the patient when possible.	**Case 93-5 (Question 1)**
⑥ Biochemical resistance to chemotherapy is the major impediment to successful treatment with most cancers. Resistance can occur de novo in cancer cells or develop during cell division as a result of mutation.	**Case 93-6 (Question 1)**
⑦ There are different types of systemic therapy: chemotherapy, targeted agents, endocrine therapy, and biologic response modifiers. Systemic therapy may be used in varying combinations and different settings. Use depends on histology, cancer stage, and the patient's predicted tolerance of the treatment.	**Case 93-7 (Question 1),** **Case 93-8 (Question 1),** **Case 93-9 (Question 1)**
⑧ Response to treatment is assessed by evaluating therapy's antitumor and toxic effects, including impact on the patient's overall quality of life. Evaluation should occur at scheduled intervals and include physical examination, laboratory tests, and repeat diagnostic imaging.	**Case 93-10 (Question 1)**
⑨ Systemic therapies used to treat cancer are potentially carcinogenic,	**Case 93-11 (Questions 1–4)**

teratogenic, or mutagenic. Handling and administering these agents poses a risk to healthcare workers. Appropriate policies and procedures must be in place to maximize safety and minimize risk while following national guidelines and standards.

INTRODUCTION TO NEOPLASTIC DISORDERS

Cancer (neoplasm, tumor, or malignancy) is not a single disease. It is a group of diseases characterized by uncontrolled growth and spread of abnormal cells. Cancer cells do not respond to the normal processes that regulate cell growth, proliferation, and survival, and they cannot carry out the physiologic functions of their normal counterparts. Other characteristics of cancer cells include their ability to invade adjacent normal tissues and break away from the primary tumor (metastasize) and travel through the blood or lymph to establish new tumors (metastases) at a distant site. Their ability to stimulate the formation of new blood vessels (angiogenesis) and their endless replication potential further contribute to their continued growth and survival.[1] Cancers can arise in any tissue in the body. If cancer cells are allowed to grow uncontrollably, they can eventually result in the death of the patient.

Cancer Statistics

Each year, the American Cancer Society publishes an estimate for the number of new cases and number of cancer-related deaths. The National Cancer Institute publishes cancer statistics that include cancer risk, prevalence, and survival information.[2] The American Cancer Society estimates that 1 of 2 American men and 1 of 3 American women will eventually develop cancer and that approximately 1,658,370 new cases of cancer will be diagnosed in 2015.[3] The most common cancers and causes of cancer-related deaths in adult Americans are listed in Table 93-1. The incidence of cancer and cancer-related deaths can be affected by both age and ethnic background, with the incidence greater in the elderly and African-American populations.[3] Other factors that are associated with an individual's increased risk for cancer include environmental and lifestyle factors, genetic predisposition, immunosuppression, and exposure to one or more potential carcinogens.[4]

Etiology

Cancers arise from the transformation of a single normal cell. Damage or mutation to the cell's DNA is caused by an initial "event." These events may include lifestyle, environmental, or occupational factors, as well as some medical therapies (e.g., cytotoxic chemotherapy, immunosuppressive or radiation therapy) and hereditary factors. Cigarette smoking is probably the single largest factor that contributes to cancer development, responsible for approximately 30% of cancer deaths per year. Other preventable causes, including physical inactivity, obesity, and nutrition, are estimated to cause an additional 30% of cancer deaths per year.[5] An estimated two million skin cancers diagnosed yearly are also potentially preventable with adequate skin protection.[6]

Cancer is a genetic disease. Two gene classes, oncogenes and tumor suppressor genes, are important in the pathogenesis of cancer. Damage to cellular DNA can result in mutations that lead to the development of oncogenes and loss or inactivation of tumor suppressor genes. Oncogenes are genes whose overactivity or presence in certain forms can lead to the development of cancer. Oncogenes arise from normal genes called proto-oncogenes through genetic alterations such as chromosomal translocations, deletions, insertions, and point mutations.

Table 93-1

Estimated Sites of New Cancer Cases and Deaths in the United States, 2015[3]

Estimated New Cases			
Males		**Females**	
Prostate	220,800 (26%)	Breast	231,840 (29%)
Lung and bronchus	115,610 (14%)	Lung and bronchus	105,590 (13%)
Colon and rectum	69,090 (8%)	Colon and rectum	63,610 (8%)
Urinary bladder	56,320 (7%)	Uterine corpus	54,870 (7%)
Melanoma of the skin	42,670 (5%)	Thyroid	47,230 (6%)
Non-Hodgkin lymphoma	39,850 (5%)	Non-Hodgkin lymphoma	32,000 (4%)
Kidney and renal pelvis	38,270 (5%)	Melanoma of the skin	31,200 (4%)
Oral cavity and pharynx	32,670 (4%)	Pancreas	24,120 (3%)

Growth and proliferation of normal cells are influenced by proteins, known as growth factors. When growth factors bind to receptors on the cell surface, they activate a series of enzymes within the cell that stimulate cell signaling pathways and gene transcription. These genes encode for proteins that regulate cell growth and proliferation. The coordination and integration of cellular signaling processes are referred to as signal transduction. Proto-oncogenes are responsible for encoding several components of signal transduction pathways, including growth factors, growth factor receptors, signaling enzymes, and DNA transcription factors. Abnormal forms or excessive quantities of these stimulatory proteins disrupt normal cell growth signaling pathways, leading to excessive growth and proliferation and, ultimately, a malignant transformation.

Tumor suppressor genes are normal genes that encode for proteins that suppress inappropriate cell division or growth. Gene deletions or mutations can cause these proteins to become inactivated, eliminating the normal inhibition of cell division. Alterations in a third class of genes, DNA repair genes, are also implicated in cancer. DNA repair genes encode for proteins that correct errors that may arise during DNA duplication. Mutations in these genes further contribute to the accumulation of genetic changes that promote cancer progression.

Cancer development is a multistep process. Therefore, multiple genetic mutations, including activation of oncogenes and loss or inactivation of tumor suppressor genes within a cell, are necessary for malignant transformation.[7] Additional genetic changes are required for tumor invasion of normal tissues and metastases.

Tumor Growth

CELL CYCLE

Cancer cells, like normal cells, proceed through a specific and orderly set of events during cellular replication referred to as the cell cycle (Fig. 93-1). The cell cycle contains four phases (M, G_1, S, and G_2), each responsible for a different task necessary for cell division. During the first activity phase, the M phase, the cell undergoes mitosis, the process of cell division. After mitosis, the cell enters the first gap or resting phase (G_1). During the G_1 resting (or gap) phase, the cell makes the enzymes necessary for DNA synthesis. The synthesis of DNA occurs during the S phase. After S phase, the cell enters a second resting phase (G_2). RNA and other proteins are synthesized to prepare for cell division during M phase. Cells that complete mitosis may either continue to proceed through the cell cycle to divide again, differentiate or mature into specialized cells and eventually die, or enter a third resting phase called G_0.[8]

Proliferation of normal cells is carefully controlled to balance the loss of mature functional cells with the production of new cells. As mentioned, proto-oncogenes and tumor suppressor genes provide the stimulatory and inhibitory signals, respectively, that regulate the cell cycle. The transition of cells through the cell cycle is an ordered, tightly regulated process, which involves a series of checkpoints that assess these signals and the number and integrity of the cells.[8] Cyclins, a group of interacting proteins found in the nucleus, and cyclin-dependent kinases (CDKs) make up the molecular machinery that regulates passage of cells through various phases of the cell cycle. The cyclins combine with CDKs to form complexes that act as molecular switches. One of these molecular switches regulates whether a cell moves through a critical restriction point that occurs late in G_1 phase to S phase. If insufficient amounts of cyclins or CDK are present during G_1 phase, the cell will not enter S phase to start cell division. Cells that pass through this restriction point are irreversibly committed to the next phase of the cell cycle.[8] A decline in the level of the CDK complex signals the end of the phase. The balance of regulation of cyclins and CDKs is influenced by several factors, including cyclin gene transcription, cyclin degradation, CDK inhibitors, and the transfer of phosphate groups to various proteins and enzymes. Activating signals from the cell's external environment are transmitted to the nucleus via growth factor receptor signaling pathways, which influence formation of cyclins and cyclin–CDK complexes. The complexes generate phosphate groups from molecules of adenosine triphosphate (ATP) and transfer them to a protein called a retinoblastoma protein (pRb). If pRb acquires enough phosphate groups, it will release the transcription factors the cell needs to make proteins essential for a cell division. In other words, phosphorylated pRb promotes cell cycle progression from G_1 to S and, subsequently, cell division. Other signaling pathways inhibit cell proliferation through endogenous CDK inhibitors, which result in dephosphorylated pRb.

Figure 93-1 Cell cycle and effects of representative cytotoxic drugs on phases of the cell cycle.

In cancer cells, the regulation and function of cyclins, CDK, and inhibitory proteins may be disrupted by malignant transformation, or these proteins can undergo changes that cause malignant transformation. Examples of defects in these processes include deletion of the Rb gene, a tumor suppressor gene that encodes for pRb, and dysregulation of the CDK through overactivation or loss of CDK inhibitors.[9] As mentioned above, pRb regulates cell cycle transition from the G_1 to the S phase and, if this molecule becomes inactive, excessive cell proliferation can occur. In normal cells, the p53 gene is responsible for temporarily arresting cell growth in response to biochemical or molecular damage until the DNA damage can be repaired.[10] If the damage cannot be repaired, apoptosis (programmed cell death) occurs to prevent genetically damaged cells from growing uncontrollably. Loss or mutation of a second tumor suppressor gene, p53, is also common in human cancers and is associated with the resistance of cancer cells to undergo cell cycle arrest or apoptosis.

Carcinogenesis

Carcinogenesis is the process by which normal cells are transformed into cancer cells. If the balance of stimulatory and inhibitory growth signals becomes dysregulated, carcinogenesis may occur. In carcinogenesis, normal mechanisms such as apoptosis and senescence (aging) do not function properly and cannot control excessive cell division. Because abnormalities in the proto-oncogenes and tumor suppressor genes regulating these processes are present in cancer cells, the balance between cell renewal and loss of mature (senescent) cells is disrupted. Cancer cells are also less dependent on receiving stimulatory signals from external growth factors.[10] Furthermore, cancer cells possess unlimited replication potential, owing to their ability to activate telomerase.[1,11] Telomerase is an enzyme that synthesizes sequences of telomeres, thereby enabling cells to proliferate endlessly. The expression of telomerase in most normal human cells is suppressed, but is reactivated in most cancer cells.[10,11] Telomeres are repeats of DNA and DNA-binding proteins that form the ends of eukaryotic chromosomes.[11] Telomere loss occurs with each successive cell replication, and after a critical length is reached, the cell undergoes irreversible growth arrest (replicative senescence).[11] Unlike normal cells, in which a finite telomere sequence regulates their life span, cancer cells are capable of immortality through their ability to maintain their telomeres indefinitely.

Metastasis

CASE 93-1

QUESTION 1: S.T., a 16-year-old boy, presented to the emergency department with a painful, swollen right leg. X-ray examination confirmed a fracture that appeared to be caused by a tumor mass in the bone. Biopsy of the bone mass confirmed osteogenic sarcoma. A chest x-ray study showed three nodules that were also believed to be malignant tumors. Does S.T. also have lung cancer or are the tumors in S.T.'s lungs metastases from the sarcoma in his leg?

S.T. does not have lung cancer. Tumor nodules in his lung are most likely metastases from the sarcoma in his leg. The ability of cancer cells to disseminate and form metastases represents their most malignant characteristic. Tumor metastases to distant sites generally have a greater effect than the primary tumor on frequency of complications and patient's quality of life. Metastases also have a greater impact than the primary tumor on mortality, with metastases associated with most cancer-related deaths. Consequently, individuals diagnosed with metastases face a worse prognosis.

Cancer cells must develop new blood vessels to obtain nutrients and spread to distant sites (metastasize). In response to low oxygen supply (hypoxia) and other factors, cancer cells and surrounding tissues secrete growth factors that stimulate growth of new blood vessels (angiogenesis) from existing blood vessels in surrounding normal host tissue. Vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and basic fibroblast growth factor (bFGF) are growth factors needed for sustained endothelial cell growth. Once released by tumor cells, these growth factors bind to tyrosine kinase receptors on the surface of endothelial cells of existing blood vessels and activate a series of intracellular relay proteins that transmit signals to genes in the nucleus to produce factors required for new endothelial cell growth.[12] Once older endothelial cells become activated by growth factors, they begin making matrix metalloproteinase (MMP) enzymes. These enzymes destroy the extracellular matrix of surrounding cells, allowing older endothelial cells to invade the extracellular matrix and begin cell division.[12] This process of invasion and proliferation is repeated several times until new blood vessels are formed.

Tumor cells can use these newly formed blood vessels to facilitate their spread to distant locations. Cells must break away from the primary tumor and travel to other sites in the body to form metastases. Normally, cells adhere to one another and the extracellular matrix. The cell-to-cell adhesion molecules are called cadherins, and the cell-to-extracellular matrix molecules are called integrins. In cancer cells, these molecules are often absent, allowing tumor cells to easily move away from the primary tumor mass.

Once a tumor cell leaves the primary mass, it travels through the blood vessels and lymphatic system within the body to form metastatic site(s). Usually, tumor cells spread to the first capillary bed they encounter after their release from the primary tumor. If the primary site drains its blood supply into the vena cava, the cancer cells will reach the capillary bed in the lung. Similarly, if the primary site drains its blood supply into the portal circulation, the cancer cells will reach the capillary bed in the liver. In addition, cancer cells can potentially pass through the first capillary bed they encounter and enter the arterial circulation where they can distribute to other organs and tissues throughout the body.

Growth conditions (e.g., growth factors, physiologic conditions) within a tissue or organ also can determine the location of a metastatic site. After a cancer cell establishes a metastatic site, it must again undergo angiogenesis to ensure continued growth. Together, angiogenesis and hematogenous or lymphatic spread help cancer cells invade healthy tissues and increase morbidity and mortality associated with the disease.

Prevention of Cancer

TOBACCO

Cigarette smoking is probably the single largest factor that contributes to cancer development, increasing risk for multiple cancer types including lung, head and neck, gastrointestinal, bladder, and cervical cancers.[5] Therefore, tobacco cessation and abstinence play an important role in prevention of cancer. For more information, visit the following page on the American Cancer Society's website: https://www.cancer.org/cancer/cancer-causes/tobacco-and-cancer.html. For review of tobacco dependence and methods for cessation see

Chapter 88, Tobacco Use and Dependence.

CHEMOPREVENTION

Chemoprevention is the use of a drug or substance to reverse, inhibit, or prevent the development of cancer. Use of chemoprevention is helpful in selected groups of high-risk patients with breast, colorectal, and prostate cancers.[13] For discussion of chemoprevention for these cancers, see Chapter 97, Breast Cancer, Chapter 99, Colorectal Cancer, and Chapter 100, Prostate Cancer.

HUMAN PAPILLOMA VIRUS (HPV) VACCINES

CASE 93-2

QUESTION 1: M.M., a 44-year-old woman, asks you about vaccines to prevent cervical cancer. Should M.M. consider vaccination for her daughter or her son? Would this substitute for Pap smear screening for her daughter?

The human papilloma virus is primarily transmitted through sexual contact; serotypes 16 and 18 (HPV-16, -18) cause approximately 70% of cervical cancers.[14] There are three different HPV vaccines available, each requiring three intramuscular injections over the course of 6 months. The HPV bivalent vaccine (Cervarix) includes HPV types 16 and 18 whereas the HPV quadrivalent vaccine (Gardasil) includes HPV types 6, 11, 16, and 18. Both vaccines demonstrated efficacy in reducing the incidence of cervical intraepithelial neoplasia (CIN), a premalignant lesion that can lead to cervical cancer.[15–17] Because the progression of HPV infection to invasive cervical cancer requires several years to possibly decades, CIN is utilized as a surrogate efficacy endpoint in HPV vaccine clinical trials. It is anticipated that the use of HPV vaccines will ultimately lead to a reduction in the incidence of cervical cancer.

The HPV 9-valent vaccine (Gardasil 9) includes the same HPV types as the bivalent and quadrivalent vaccines (6, 11, 16, 18) but with five additional HPV types (31, 33, 45, 52, 58), increasing prevention to approximately 90% of cervical cancers.[18] The HPV quadrivalent and 9-valent vaccines are also approved for the prevention of vulvar intraepithelial neoplasia (VIN) and vaginal intraepithelial neoplasia (VAIN) in females as well as prevention of HPV-related genital warts and anal cancer in males. However, there are no data to support the use of these vaccines to prevent other cancers associated with HPV, such as penile cancer or head and neck cancers.

Routine Pap smear and HPV screening should continue for vaccinated women because the vaccines do not prevent all oncogenic types of HPV. The duration of vaccine-induced anti-HPV immunity is also unknown.

M.M. should consider HPV vaccination for her daughter. All three vaccines are indicated in females of 9 to 26 years of age, but the vaccines are most effective if initiated before sexual activity. Whether or not M.M.'s daughter is vaccinated, she should still receive routine Pap smear screening according to current guidelines.[19] The HPV quadrivalent and 9-valent vaccines are approved in males of 9 to 26 years of age; therefore, M.M. should also consider vaccination for her son. The Centers for Disease Control recommends HPV vaccination for all females and males at the age of 11 to 12 years.[20]

DIET

Diet has been linked to the development of colon, prostate, and breast cancers. The American Cancer Society advocates a healthy diet that consists of vegetables, fruit, whole grains, and fiber and is low in fat and red meat.[21] For more information, visit the following page on the American Cancer Society's website: http://www.cancer.org/Cancer/CancerCauses/DietandPhysicalActivity/index.

Migrant studies suggest that diet, environmental, or social factors play a role in the development of prostate cancer and that the incidence of colon cancer in a population increases as individuals migrate from a low-incidence region to a high-incidence region.[22,23] In women, the risk of breast cancer is increased with obesity and physical inactivity, but an association with a high-fat diet is less clear.[24] Moderate alcohol consumption has also been associated with an increased risk of breast cancer.[25] For more information, visit the following page on the American Cancer Society's website: http://www.cancer.org/Healthy/EatHealthyGetActive/index.

SUN AND ULTRAVIOLET RADIATION EXPOSURE

Most risk factors associated with skin cancer are uncontrollable, with the exception of sun exposure and other forms of ultraviolet (UV) radiation. The interaction between UV radiation and skin cancers is complex, because nonmelanomas (e.g., basal cell and squamous cell carcinomas) are associated with cumulative UV radiation exposure and certain cutaneous melanomas are associated with excessive, intermittent UV radiation exposure.[26] The risk of melanoma is further increased in people who have a history of five or more severe sunburns in their lifetime, particularly during adolescence, or history of tanning bed use.[26,27] Depletion of the ozone layer in the stratosphere may also contribute to the increased incidence of melanoma.[26]

Prevention of skin cancer is based on limiting sun and UV radiation exposure. The American Cancer Society guidelines recommend avoiding or limiting sun exposure from 10 AM to 4 PM when the UV rays are the strongest, and avoiding tanning bed or sun lamp use. Protective clothing (hat, sunglasses, long-sleeved shirt, pants) and sunscreens are also advised to minimize exposure.[27] However, the protective effects of sunscreens alone against melanoma, particularly for intentional sun exposure, are controversial and should not be used to prolong time in the sun.[27,28]

Screening and Early Detection of Cancer

Standardized screening tests help identify disease in asymptomatic individuals (screening) or diagnose disease in symptomatic individuals (early detection). The cancer screening tests recommended by the American Cancer Society meet four basic requirements: (a) There must be good evidence that the test is effective in reducing morbidity or mortality; (b) benefits of the test should outweigh its risks; (c) costs of the test should be in balance with its presumed benefits; and (d) the test should be practical and feasible within the existing healthcare setting. For more information, visit the following page on the American Cancer Society's website: http://www.cancer.org/Healthy/FindCancerEarly/CancerScreeningGuidelines/an
cancer-society-guidelines-for-the-early-detection-of-cancer.

Screening guidelines are updated frequently, and newest guidelines should be consulted when counseling patients. Professional organizations including the American Cancer Society (http://www.cancer.org) and National Comprehensive Cancer Network (NCCN) (http://www.nccn.org) regularly publish recommendations for screening of breast, cervical, colon, lung, and prostate cancers.[29]

Diagnosis and Staging of Cancer

The histologic diagnosis of a tumor is the most important determinant of treatment selection. This is because its histologic classification influences its natural history, pattern of progression, and responsiveness to treatment. A biopsy followed by a microscopic and biochemical evaluation by a pathologist can provide the most accurate histologic diagnosis. Thereafter, staging can begin.

CASE 93-3

QUESTION 1: J.S. is diagnosed with breast cancer after a biopsy of a large breast mass. Chemotherapy, radiation, and surgery are commonly used to treat patients diagnosed with breast cancer. What information is needed to select a treatment plan for J.S.?

The stage of the cancer, as well as the histologic diagnosis, influences both the treatment selection and prognosis. Staging is the process that determines the extent or spread of the disease.

Determining the stage of the cancer typically requires tests that can physically or radiographically measure the size of the primary tumor and assess for evidence of tumor spread (e.g., radiographs, computed tomography [CT] scans, magnetic resonance imaging [MRI] scans, or positron emission tomography [PET] scans) and pathologically examine regional lymph nodes.[30] Clinicians also evaluate symptoms (e.g., pain) or signs (e.g., swelling, abnormal laboratory findings) that may indicate tumor involvement at a distant site. Common sites of tumor metastases are shown in Table 93-2.

Staging schemas have been developed for all major types of cancers. For solid tumors, the most widely used and accepted staging classification is the TNM system, which incorporates the size of the primary tumor (T), the extent of regional lymph node spread (N), and the presence or absence of metastatic spread to distant organs (M). Within each TNM category, the extent of cancer involvement is related to prognosis. Most solid tumor staging systems also incorporate the TNM classification into broader groups, called stages, to facilitate treatment decisions and comparison among patient populations. Classification of stages differs among solid tumors types. Please refer to malignancy-specific chapters for TNM staging of breast, lung, prostate, and colorectal cancers.

Whereas the TNM system enables staging of solid tumors, it does not enable staging for hematologic malignancies, including leukemias, lymphomas, and multiple myeloma. Because hematologic malignancies occur in the blood cells and lymphatic tissues that are widely distributed throughout the body, the TNM staging system cannot sufficiently describe these diseases. To define the extent of disease, guide treatment, and provide prognostic information, specific staging systems have been developed for various hematologic malignancies. Staging systems for hematologic malignancies are discussed in further detail in Chapter 96, Adult Hematologic Malignancies.

Table 93-2

Common Sites of Metastases for Selected Tumors

Cancer Type	Common Sites of Metastases
Breast	Bone (osteolytic lesions), lung, liver, brain. ER-positive tumors preferentially spread to bone; ER-negative tumors may metastasize to visceral organs
Lung	Liver, brain, adrenals, pancreas, contralateral lung, and bone
Prostate	Bone (osteoblastic lesions)
Colon	The portal circulation pattern favors dissemination to the liver and peritoneal cavity, but metastasis also occurs in the lungs
Ovarian	Local spread in the peritoneal cavity
Myeloma	Bone (osteolytic lesions), sometimes spreading to other organs

ER, estrogen receptor.

Staging systems for some tumors also include other characteristics to further determine the stage and prognosis of the disease, such as clinical signs and symptoms, biochemical characteristics of the tumor, or other laboratory tests. For example, the staging system used for Hodgkin lymphoma includes constitutional symptoms (i.e., fever, night sweats, and weight loss). These symptoms confer a poorer prognosis and could indicate the need for more intensive therapy.

Tumor staging is done at the time of initial diagnosis and periodically during treatment to assess the patient's response to therapy. Staging should also be repeated (a) when evidence shows that the cancer has progressed during treatment or recurred after therapy to establish the most appropriate next-line therapy, and (b) to enable measurement of response to that therapy.

J.S. needs to undergo the appropriate imaging scans, laboratory studies, and clinical evaluation so that her breast cancer can be staged. These tests may include blood tests (e.g., complete blood cell and platelet count, liver function tests), mammograms or breast ultrasounds, determination of tumor ER/PR and HER2 status, breast MRI, bone scan, abdominal scans, and chest imaging. Once staging is completed, treatment recommendations and options can then be determined. Treatment options for breast cancer based on stage are further discussed in Chapter 97, Breast Cancer.

CLINICAL PRESENTATION AND COMPLICATIONS OF MALIGNANCY

The initial signs and symptoms of malignant disease are variable and predominantly depend on histologic diagnosis, location (including metastases), and size of the tumor. Pain secondary to compression, obstruction, and destruction of adjacent tissues and organs is the most common presenting symptom. Other common initial symptoms reported by patients with cancer include anorexia, weight loss, and fatigue. Certain symptoms, however, may be obscured by a concomitant illness, such as chronic lung disease in patients with lung cancer. Some tumors cause signs and symptoms early in the course of the disease, whereas others may not cause symptoms until late in the course of the disease and after significant tumor growth. In either of these circumstances, early diagnosis may be difficult. Individuals at a higher-than-average risk for certain malignancies should be screened regularly to help detect early disease. Tumor involvement of the liver, kidneys, or lungs can complicate therapy by causing significant organ dysfunction and metabolic disturbances. In addition, compression or obstruction could produce a "mass effect" by impairing normal organ or tissue function and causing pain or other uncomfortable physical effects. Life-threatening complications that require immediate intervention include obstruction of the superior vena cava, spinal cord compression, and brain metastases.

CASE 93-4

QUESTION 1: P.N., a 59 year-old woman, presents with shortness of breath, fatigue, anorexia, weight loss, and abdominal pain and distension that have worsened significantly during the previous 3 weeks. A CT scan of her abdomen shows a large mass surrounding the head of her pancreas with biopsy results that confirm pancreatic adenocarcinoma. The staging workup confirms the presence of distant metastases. Her husband states that she was previously an active person, but that she most recently has been unable to dress herself or participate in normal daily activities. He states that she spends most of the day in bed. Will her activity level influence the type of treatment that she can receive?

Cancer can have a profound effect on a patient's quality of life and his/her ability to tolerate appropriate therapy. Patients with malnutrition secondary to anorexia, mechanical obstruction, or pain may not tolerate some therapies because of significant physical

---

debility. Performance status is a measure of functional capacity and reflects a patient's ability to ambulate, care for himself/herself, and carry out normal activities. For several cancers, poor pretreatment performance status is associated with decreased ability to tolerate treatment, decreased tumor response to treatment, and worsened clinical outcome. In these cases, especially if the cancer is not known to respond well to treatment, a less aggressive treatment regimen may be recommended. For this reason, performance status is important to assess at the time of staging evaluation and periodically during treatment. Different scales (i.e., Karnofsky score, Eastern Cooperative Oncology Group [ECOG]) can be used to determine performance status. The Karnofsky and ECOG performance scales are depicted in Table 93-3.[31] Because P.N. has a poor performance status (ECOG grade 3) and may not tolerate chemotherapy well, her oncologist may recommend a less toxic treatment plan. Because other conditions, such as depression, could contribute to her symptoms, P.N. should undergo comprehensive evaluation.

TREATMENT

CASE 93-5

QUESTION 1: T.J., a 40-year-old man with no significant medical history, presents to his physician with complaints of abdominal pain, nausea and vomiting, weakness, and weight loss. On physical examination, he is noted to be slightly jaundiced. A CT scan of his abdomen reveals a mass present in the peripancreatic area that is suggestive of malignancy. Once diagnosed and staged, T.J. asks the surgeon how will this malignancy be treated? And what is the goal of therapy?

The choice of specific therapy and its goals depends not only on the histology and stage of the cancer but also on the patient's predicted tolerance of the side effects of the various treatment options. The goal of therapy should always be to cure the patient when possible. The likelihood of cure is greater when the tumor burden is low (i.e., lower stage). When using therapy with curative intent is not possible, therapy becomes palliative in nature, with disease control and symptom management the priority. Goals of therapy should be balanced so that quantity and quality of life are both adequately considered.

Cancer is predominately treated with three modalities: surgery, radiation, and systemic therapy (including chemotherapy, targeted therapy, biologic response modifiers, etc.). Systemic therapy is the primary treatment modality for hematologic malignancies. In most solid tumor malignancies, early-stage and localized disease is treated with either surgery or radiation therapy. Sometimes, combinations of modalities may be used to maximize the potential for cure or disease control (e.g., radiation given in combination with chemotherapy). For advanced disease (presence of metastases or recurrence after initial therapy), solid tumor malignancies are usually treated with systemic therapy as the primary treatment modality. T.J.'s treatment will be dependent on tumor histology, stage, and expected prognosis. If T.J. has potentially curable disease, he should be treated with curative intent therapy, whereas if T.J. has advanced disease that denotes a poor prognosis, he should be treated with palliative therapy.

Surgery

Surgery is an important treatment option for patients diagnosed with certain solid tumors. With the recent advances in surgical techniques (e.g., minimally invasive procedures) and improved understanding of patterns of tumor growth and spread, successful resections are possible for an increasing number of patients. Surgery may be used as preventive therapy (e.g., removal of colonic polyps or cervical dysplasia) or diagnostic treatment, or staging of some cancers.

Table 93-3

Performance Status Scales[31]

Eastern Cooperative Group (ECOG)		**Karnofsky**	
Grade	**Description**	**Grade**	**Description**
0	Fully active, able to carry on all predisease performance without restriction	100	Normal, no complaints; no evidence of disease
		90	Able to carry on normal activity; minor signs or symptoms of disease
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature	80	Normal activity with effort, some signs of symptoms of disease
		70	Cares for self but unable to carry on normal activity or do active work
2	Ambulatory and capable of all self-care but unable to carry out any work activities. Up and about more than 50% of waking hours	60	Requires occasional assistance but is able to care for most of personal needs
		50	Requires considerable assistance and frequent medical care
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours	40	Disabled; requires special care and assistance
		30	Severely disabled; hospitalization is indicated

			although death not imminent
4	Completely disabled. Cannot carry on any self-care. Totally confined to bed or chair.	20	Very ill; hospitalization and active supportive care necessary
		10	Moribund
5	Dead	0	Dead

Surgery can be used to manage both localized and advanced tumors. When surgery provides curative therapy for a localized tumor, the surgeon removes the tumor plus a margin of normal tissue surrounding the tumor. For extensive, localized tumors that cannot be completely removed, selected patients may undergo cytoreductive surgery to resect the tumor partially in an attempt to improve the likelihood that subsequent chemotherapy or radiation therapy may successfully kill the tumor.

Patients with metastatic disease may have palliative surgery to relieve pain or improve functional abnormalities caused by the advanced tumor (e.g., gastrointestinal obstruction). Palliative surgery may improve quality of life without prolonging survival.

Radiation

Radiation may be administered as either curative or palliative therapy for solid tumors. Radiation is administered in varying doses depending on the type of tissue (e.g., bone, lung, breast, liver, brain) being treated and the intent of therapy (palliative or curative). A limit exists to the total amount of radiation that can be delivered to the area being treated dependent on the type of tissue. Damaging effects of radiation on the normal tissues that surround the tumor can be dramatic, and may be exacerbated if given concomitantly with chemotherapy. Chemotherapy that follows completion of radiation therapy can produce “radiation recall” of local toxicity that manifests as skin redness, swelling, and peeling at the radiation site.

Not all cancers are sensitive to radiation, so this modality has limited application in these cases. For radiation-sensitive tumors (Table 93-4), potential advantages exist over surgery. For instance, radiation therapy may encompass a wider area around the tumor and treat tumors in regions of the body where surgery cannot safely be performed. Radiation therapy also can be used when surgery could result in considerable disability or disfigurement. Patients may receive radiation therapy to multiple sites simultaneously.

Multiple methods are used to administer radiation to tumors. External-beam radiotherapy and brachytherapy are two types that are commonly used. Newer radiation therapy techniques, including intraoperative radiation, hyperfractionated radiation, stereotactic radiosurgery, intensity-modulated radiation therapy, charged-particle (proton) radiation therapy, and computerized three-dimensional conformal treatment planning, may reduce associated toxicities, enhance tumor responsiveness, and improve the clinical usefulness of radiation.[32,33]

Table 93-4

Cancers Frequently Treated with Radiation Therapy

Acute lymphocytic leukemia (central nervous system radiation)
Brain and central nervous system
Breast
Head and neck cancers, squamous cell
Lung
Lymphomas
Neuroblastoma
Prostate
Rectal
Testicular, seminoma

Systemic Therapy

Not all cancers can be treated by surgery or radiation therapy. Patients may present with widespread metastatic disease at diagnosis or recur following primary treatment with surgery or radiation. Patients may also have residual tumor following initial surgery or radiation, requiring additional treatment. In these circumstances, systemic treatments including chemotherapy, targeted therapy, endocrine therapy, and biologic response modifiers generally offer the only hope of controlling disease.

CHEMOTHERAPY

The National Cancer Institute defines chemotherapy as drugs that treat cancer cells.[34] For the purposes of this chapter, chemotherapy will be defined as cytotoxic therapy that is directed toward rapidly dividing cells. Chemotherapy kills cancer cells by damaging DNA, interfering with DNA synthesis, or inhibiting cell division. Chemotherapy agents are classified by their effect on the cell cycle or mechanism of action. Agents that affect a specific phase of the cell cycle are referred to as phase-specific agents or schedule-dependent agents. In contrast, agents that affect any phase of the cell cycle are referred to as phase-nonspecific agents or dose-dependent agents (Fig. 93-1). The specific mechanisms of action for several chemotherapy agents are described in Table 93-5.[35]

Factors that Influence Response to Chemotherapy

Cell Kill

Studies using rodent animal models during the 1960s demonstrated that the number of tumor cells killed by chemotherapy is proportional to the dose when the growth fraction is 100% (i.e., all cells are dividing) and the tumor cells are sensitive to the agent.[36,37] For example, if a dose of chemotherapy reduces the tumor burden from 10^{10} to 10^8 cells, the same dose administered when only 10^7 cells are present should reduce the tumor burden to 10^5 cells. This theory has become known as the cell-kill or log-kill hypothesis (Fig. 93-2).

In the clinical setting, tumor cells do not always decrease predictably with each successive course of chemotherapy. This is because the growth fraction of human tumors is not 100% and the cell population is heterogeneous, with some cells that are resistant to chemotherapy.

Dose Intensity

Dose intensity is defined as the chemotherapy dose per unit time during which treatment is given (e.g., mg/m^2/week). Drug resistance might be overcome by increasing the dose of chemotherapy. Evidence suggests that reducing a dose can cause treatment failure in patients with chemotherapy-sensitive tumors who are having their first chemotherapy treatment.[38] A direct relationship between dose intensity and response rate also has been reported in several human tumors including breast cancer, lymphomas, ovarian cancer, and small-cell lung cancer.[39,40] However, dose-intensive therapy has not consistently improved the overall cure rate of most solid tumors.

The dose intensity for most chemotherapy regimens is limited by the major dose-related toxicity, bone marrow suppression. To minimize this toxicity and administer higher doses, patients may receive hematopoietic growth factors, autologous stem cell transplantation, or altered schedules of drug delivery.[41,42]

Schedule Dependency

Chemotherapy is administered in cycles (e.g., every 2, 3, or 4 weeks) with recovery periods between cycles. A typical course of chemotherapy usually consists of several cycles. The interval of time between cycles depends on the type of cancer and the drugs being used.

Table 93-5

Chemotherapy Agents

Subclass	Agent (Trade Name)	Mechanism of Action	Route of Administration	Notable Toxicities
Alkylating Agents				
Nitrogen mustards (and related agents)		Cross-links DNA strands leading to cell death		Myelosuppression; nausea, vomiting; fatigue

	Bendamustine (Treanda)	Nitrogen mustard analog	IV	Also: hepatic dysfunction; fever; headache
	Chlorambucil (Leukeran)		PO	Also: rash; hepatic dysfunction; pulmonary fibrosis; myoclonus, hallucinations
	Cyclophosphamide (Cytoxan)		IV, PO	Also: immunosuppression; hemorrhagic cystitis; alopecia; cardiomyopathy
	Ifosfamide (Ifex)		IV	Also: hemorrhagic cystitis (coadministered with mesna); encephalopathy; alopecia
	Melphalan (Alkeran)		IV, PO	Also: stomatitis
	Thiotepa (Thioplex)	Ethylenimine-type related to nitrogen mustard	IV, IT, intracavitary	Also: anaphylaxis, rash, blurred vision; dizziness; alopecia
Nitrosoureas		Interferes with normal cellular function via cross-linking of DNA and RNA strands		Myelosuppression; nausea, vomiting; pulmonary toxicity; hepatic and renal dysfunction
	Carmustine (BiCNU)		IV, brain implant	
	Lomustine (CeeNU)		PO	Also: ocular changes
Platinum analogs		Reacts with nucleophilic sites on DNA forming cross-links		Myelosuppression, nausea, vomiting; peripheral neuropathy; delayed hypersensitivity reactions; secondary malignancy
	Carboplatin (Paraplatin)		IV	Also: electrolyte abnormalities
	Cisplatin (Platinol)		IV, IP	Also: renal dysfunction; ototoxicity; electrolyte abnormalities; vesicant
	Oxaliplatin (Eloxatin)		IV	Also: sensitivity to cold, jaw spasm, dysphagia; diarrhea; pulmonary fibrosis
Triazenes		Alkylates DNA leading to double-strand breaks and cell death		Myelosuppression; nausea, vomiting, anorexia; fatigue; headache; alopecia
	Dacarbazine (DTIC-Dome)	Prodrug (activated by CYP)	IV	Also: flu-like syndrome
	Temozolomide (Temodar)	Prodrug of dacarbazine (spontaneously hydrolyzed)	IV, PO	Also: constipation
Other				
	Busulfan	Cross-links DNA	IV, PO	Myelosuppression; pulmonary

	(Myleran, Busulfex)	strands, interfering with normal function		fibrosis; hyperpigmentation; hepatic dysfunction; seizures and veno-occlusive disease (high dose)
	Procarbazine (Matulane)	Inhibits DNA and RNA synthesis through transmethylation of methionine	PO	Myelosuppression; nausea, vomiting; neurologic toxicity; hepatic dysfunction; secondary malignancy

Antimetabolites				
DNA demethylation agents		Incorporates into RNA and DNA and inhibits methylation		Myelosuppression; nausea, vomiting, diarrhea; bruising, petechiae; fatigue, fever
	Azacitidine (Vidaza)		IV or SC	Also: injection-site reaction
	Decitabine (Dacogen)		IV	Also: electrolyte abnormalities; edema; psychiatric changes
	Nelarabine (Arranon)		IV	Also: somnolence, dizziness, seizure, peripheral neuropathy; edema
Folic acid antagonists		Inhibits dihydrofolate reductase; interferes with DNA synthesis, repair, and cellular replication		Myelosuppression; stomatitis; nausea; fatigue; hepatic dysfunction
	Methotrexate (Trexall)		IV, PO	Also: renal dysfunction; photosensitivity; pulmonary toxicity; neurotoxicity
	Pemetrexed (Alimta)	Also: inhibits additional enzymes involved in folate metabolism	IV	Also: rash
	Pralatrexate (Folotyn)	Also: selectively enters cells expressing reduced folate carrier-1	IV	Also: fever; edema; diarrhea; cough, rash
Purine analogs		Inhibits DNA synthesis and repair by incorporating into DNA		Myelosuppression; nausea, vomiting, anorexia; fatigue
	Cladribine (Leustatin)	Prodrug (intracellular phosphorylation)	IV	Also: fever; fatigue; headache; rash; injection-site reaction

	Clofarabine (Clolar)	Also: inhibits ribonucleotide reductase	IV	Also: headache; rash, pruritus; anxiety; fever; tachycardia, hypotension; diarrhea; hepatic and renal dysfunction
	Fludarabine (Fludara)	Also: inhibition of DNA polymerase and ribonucleotide reductase	IV	Also: fever, chills; edema; cough; rash
	Mercaptopurine (Purinethol)	Also: S phase specific; converted to a ribonucleotide	PO	Also: rash; drug fever; hepatic dysfunction
	Thioguanine (Tabloid)	Also: complete cross-resistance with mercaptopurine	PO	Also: hepatotoxicity, veno-occlusive disease; stomatitis; hyperuricemia; fluid retention
Other				
	Hydroxyurea (Hydrea, Droxia)	Holds cells in the G_1 phase of cell cycle	PO	Myelosuppression; dermatologic toxicity; nausea, vomiting, diarrhea
Pyrimidine analogs		Incorporates into RNA and DNA; interferes with RNA function		Myelosuppression; nausea, vomiting, stomatitis, diarrhea
	Capecitabine (Xeloda)	Also: prodrug metabolized to fluorouracil; inhibits thymidylate synthase	PO	Also: hand-foot syndrome; anorexia
	Cytarabine (Cytosar-U, Ara-C)	Also: inhibits DNA polymerase	IV, IT (liposomal)	Also: cytarabine syndrome (fever, myalgia, bone pain, rash, conjunctivitis); hepatic dysfunction
	Fluorouracil (Adrucil)	Also: inhibits thymidylate synthase	IV	Also: alopecia; hand-foot syndrome

	Gemcitabine (Gemzar)	Also: inhibits DNA polymerase and ribonucleotide reductase	IV	Also: flu-like syndrome; rash, edema
Antimitotic Agents				
Epothilones		Binds directly to β-tubulin; promotes stabilization of microtubles		Alopecia; myelosuppression; peripheral neuropathy; arthralgia, myalgia; stomatitis, nausea, vomiting, diarrhea
	Ixabepilone (Ixempra)		IV	

Taxanes (and related agents)		Binds to β-tubulin; promotes stabilization and suppresses disassembly of microtubules		Myelosuppression; alopecia; nausea, vomiting, diarrhea; peripheral neuropathy; myalgia, arthralgia; fatigue
	Cabazitaxel (Jevtana)		IV	
	Docetaxel (Taxotere)		IV	Also: hand-foot syndrome; edema; hypersensitivity reaction
	Paclitaxel (Taxol)		IV, IP	Also: hypersensitivity reaction
	Paclitaxel, albumin-bound (Abraxane)		IV	
Vinca alkaloids		Binds to tubulin interfering with microtubule assembly and mitotic spindle formation		Myelosuppression; constipation; bone pain; neurotoxicity, neuropathies; vesicant
	Vinblastine (Velban)		IV	
	Vincristine (Vincasar, Oncovin)		IV	Also: autonomic neuropathies (high dose); fever; nausea; constipation; SIADH
	Vinorelbine (Navelbine)		IV	Also: fatigue; liver dysfunction
Halichondrin B analog		Disrupts microtubule polymerization		Myelosuppression; alopecia; nausea, constipation; peripheral neuropathy; fatigue
	Eribulin (Halaven)		IV	
Other				
	Estramustine (Emcyt)	Stabilizes microtubule formation	PO	Gynecomastia; hepatic dysfunction; edema; nausea, diarrhea
Antitumor Antibiotics				
Anthracyclines		Stabilizes the cleavable complex between topoisomerase II and DNA, causing single- and double-strand DNA breaks		Myelosuppression; mucositis; alopecia; nausea, vomiting; cumulative cardiac toxicity; secondary malignancy
	Daunorubicin (Cerubidine)		IV	Also: vesicant
	Daunorubicin, liposomal (DaunoXome)		IV	Also: diarrhea; fatigue, rigors, neuropathy; dyspnea
	Doxorubicin		IV	Also: acute cardiac toxicity;

	(Adriamycin, Rubex)			vesicant
	Doxorubicin, liposomal (Doxil)		IV	Also: fatigue; stomatitis; rash, hand-foot syndrome
	Epirubicin (Ellence)		IV	Also: mucositis, alopecia; vesicant
	Idarubicin (Idamycin)		IV	Also: diarrhea; alopecia; vesicant
	Valrubicin (Valstar)		Intravesical	Urinary urgency; urinary frequency, dysuria, hematuria
Other				
	Bleomycin (Blenoxane)	Binds to DNA, producing single- and double- strand DNA breaks	IV	Erythema, hyperpigmentation; pulmonary toxicity; fever, chills
	Dactinomycin (Cosmegen)	Intercalates DNA, inhibiting DNA synthesis and DNA-dependent RNA synthesis	IV	Myelosuppression; nausea, vomiting; hepatic dysfunction; vesicant; radiation recall
Miscellaneous				
Cephalotaxine		Inhibits ribosome function, impairing protein synthesis		Myelosuppression; diarrhea, nausea; infusion-related reaction, injection-site reaction; hyperuricemia; infection, fever, fatigue
	Omacetaxine (Synribo)		SC	
Differentiation Agents		Promotes myeloid differentiation and maturation		Nausea, vomiting, diarrhea; dermatologic toxicity; headache, fatigue, edema; bone pain
	Arsenic trioxide (Trisenox)	Also: causes morphologic changes and DNA fragmentation	IV	Also: RA-APL syndrome, myelosuppression, leukocytosis; cardiac effects; psychiatric changes; electrolyte abnormalities
	Tretinoin (Vesanoid)		PO	Also: RA-APL syndrome, leukocytosis; cardiac effects; psychiatric; lipid abnormalities
	Bexarotene (Targretin)		PO	Also: lipid abnormalities; hypothyroidism; myelosuppression
DNA Topoisomerase Inhibitors		Inhibits topoisomerases, leading to DNA		Myelosuppression, fatigue; alopecia

		strand breaks		
	Etoposide (VePesid)	Inhibits topoisomerase II	IV, PO	Also: nausea, vomiting; hypersensitivity reaction; secondary malignancy
	Irinotecan (Camptosar)	Inhibits topoisomerase I	IV	Also: diarrhea, cholinergic syndrome; hepatic dysfunction
	Topotecan (Hycamtin)	Inhibits topoisomerase I	IV, PO	Also: nausea, vomiting, diarrhea
Other				
	Asparaginase (Elspar, Erwinase)	Depletes asparagine, leading to inhibition of protein synthesis	IV	Hypersensitivity reaction; nausea, vomiting; decreased clotting factors; renal dysfunction

CYP, cytochrome; DNA, deoxyribonucleic acid; IP, intraperitoneal; IT, intrathecal; IV, intravenous; PO, oral; RA-APL, retinoic acid–acute promyelocytic leukemia; RNA, ribonucleic acid; SC, subcutaneous; SIADH, syndrome of inappropriate antidiuretic hormone.

The optimal schedule is also influenced by the pharmacokinetics of the agent. For example, phase-specific agents exert their cytotoxic effects only when the cell is in a particular phase of the cell cycle. If a phase-specific agent with a short half-life is administered by intravenous bolus, a significant number of tumor cells will not be in the vulnerable phase of the cell cycle during exposure to the agent. Comparatively, the same agent administered by frequent intravenous bolus or continuous infusion could expose more cells to the agent during the vulnerable phase.[43]

Drug Resistance

CASE 93-6

QUESTION 1: B.C. is a 39-year-old male with aggressive non-Hodgkin lymphoma (NHL). At the time of diagnosis, B.C. had enlarged cervical lymph nodes, dyspnea, and a large mediastinal mass noted on chest x-ray examination. Chemotherapy was initiated with rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (RCHOP). After the first cycle of chemotherapy, B.C.'s lymphadenopathy was greatly reduced. Chest x-ray examination repeated after the second cycle of therapy showed marked improvement. When he returned for his fifth cycle of chemotherapy, recurrent lymphadenopathy was noted and the chest radiograph confirmed enlargement of the mediastinal mass. Why is B.C.'s cancer growing despite continued chemotherapy and how should his treatment be altered?

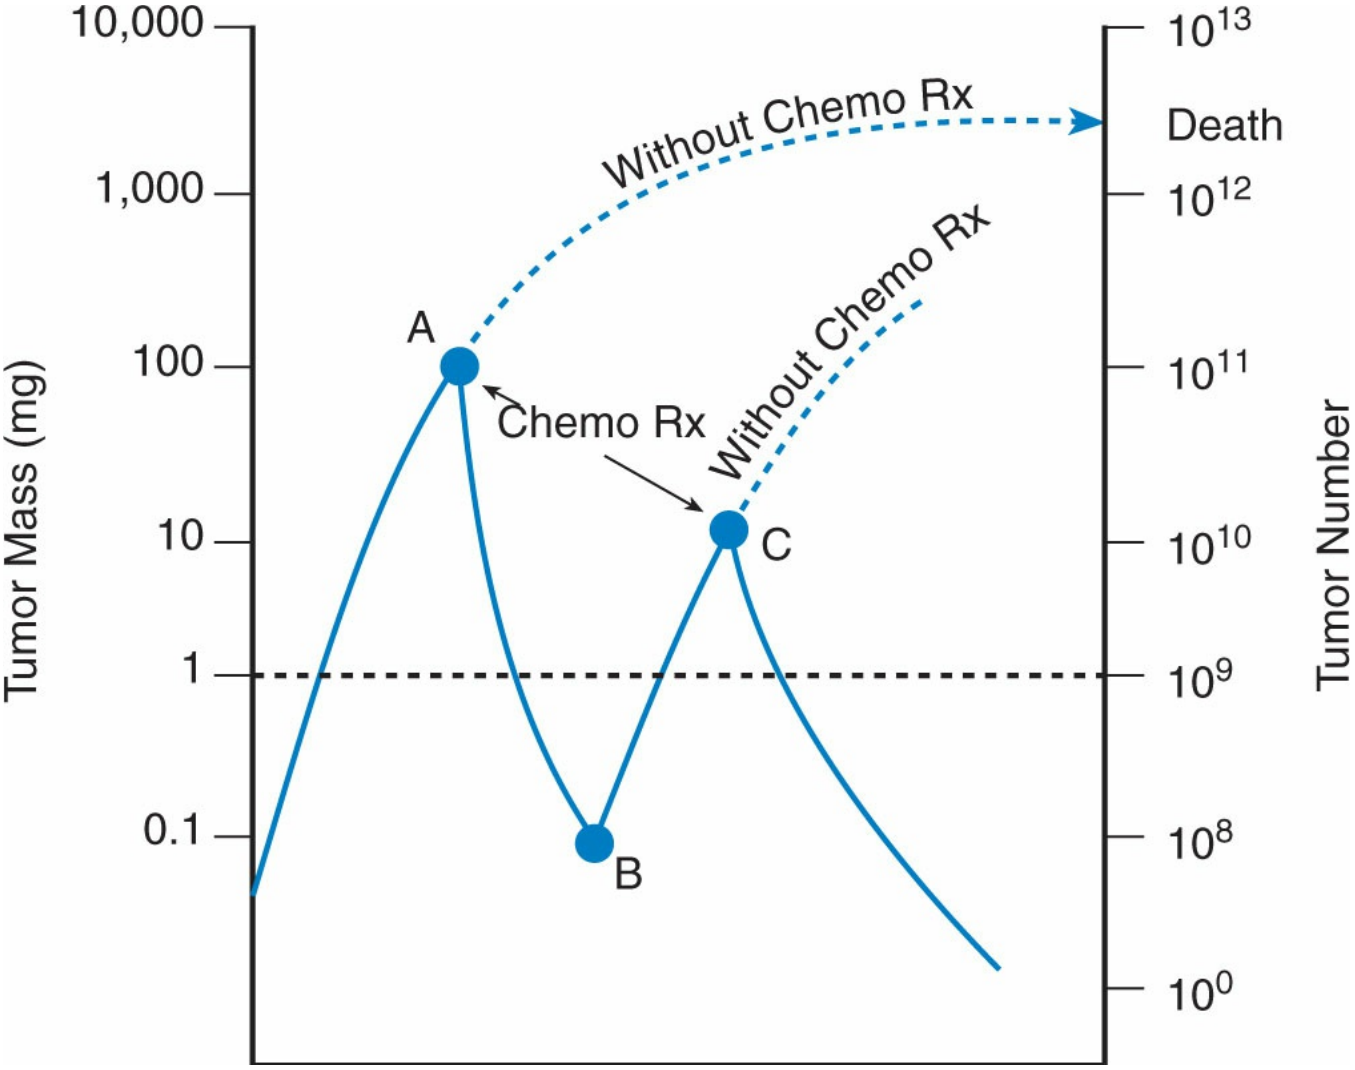

Figure 93-2 Log-kill hypothesis. The growth rate of a tumor is initially very rapid and eventually slows as it approaches 10^{11} cells. Two trillion (2×10^{12}) cells or 2 kg of tumor is lethal to humans. An effective chemotherapy treatment (Chemo Rx) given at point A will decrease the tumor number to point B. Regrowth of the tumor will occur during the recovery period until further chemotherapy is given at point C.

Most likely, B.C.'s cancer is now growing because the tumor has become resistant to the chemotherapy. Therefore, it would be wise to discontinue the current regimen. Biochemical resistance to chemotherapy is the major impediment to successful treatment with most cancers.[38] Resistance can occur de novo in cancer cells or develop during cell division as a result of mutation.[38] In 1979, a proposed mathematical model known as the Goldie–Coldman hypothesis predicted that tumor cells mutate at a rate related to the genetic instability of the tumor.[44] Thus, the probability that a tumor mass will contain resistant clones is related to both the rate of mutation and the size of the tumor. Many mechanisms have been identified by which cancer cells resist the activity of cytotoxic agents.

Some cell lines that become resistant to a single chemotherapy agent may also be resistant to structurally unrelated cytotoxic compounds. This phenomenon is called pleiotropic drug resistance or multidrug resistance (MDR).[45] Cell lines that display this type of resistance are generally resistant to natural product cytotoxic agents such as the vinca alkaloids, antitumor antibiotics, epipodophyllotoxins, camptothecins, and taxanes. The primary mechanism believed to be responsible for MDR is an increase in efflux transporters such as P-glycoprotein in the cell membrane. These proteins mediate efflux of the chemotherapy agent, causing decreased accumulation of drug within the cell and decreased cytotoxicity.[45] Other transport proteins (e.g., breast cancer resistance protein) have been implicated in resistance to chemotherapy as well.[46]

Another type of MDR is resistance caused by changes or mutations of drug targets, for example, the altered binding of topoisomerase II, an enzyme that promotes DNA strand breaks in the presence of anthracyclines and epipodophyllotoxins.[47] Because of the likelihood of MDR, B.C. should receive a chemotherapy regimen that does not include agents transported from tumor cells by the MDR mechanism. An alternative regimen such as gemcitabine or oxaliplatin, with or without rituximab, may be a reasonable option because this regimen is active against NHL and these drugs are not known substrates for various efflux transporters.

Tumor Site

The cytotoxic effects of chemotherapy agents are related to the time the tumor is exposed to an effective concentration of the agent (i.e., concentration × time [C × T]). The drug dose, infusion rate, route of administration, lipophilicity, and protein binding can influence the concentration–time product. Other factors, such as tumor size and location, can also critically affect an agent's cytotoxicity. As tumors grow larger, their degree of vascularity lessens, making it more difficult for agents to penetrate the entire tumor mass. Tumors located in sites of the body with poor drug penetration (e.g., the brain) may not receive a sufficient concentration to provide effective kill.

Pharmacogenetics

Antitumor activity and adverse effects of chemotherapy agents are associated with the presence of genetic polymorphisms that can affect the metabolism and disposition of drug. See Chapter 97, Breast Cancer, and Chapter 99, Colorectal Cancer, for a more detailed discussion of genetic polymorphisms associated with UGT1A1, CY2D6, and HER2/neu receptor positivity.

Combination Chemotherapy

CASE 93-7

QUESTION 1: K.K. has newly diagnosed stage II, bulky Hodgkin lymphoma. She initially presented with asymptomatic lymphadenopathy, night sweats, and a 15% weight loss in the previous 2 months. K.K. is to begin chemotherapy today with doxorubicin, bleomycin, vinblastine, and dacarbazine. All of these chemotherapy agents have activity in Hodgkin lymphoma. Why is it recommended that K.K. receive all four drugs, rather than just one drug?

Although single-agent chemotherapy can cause significant early regression of

Hodgkin lymphoma, acute lymphocytic leukemia, and adult NHL, some tumors show only a partial, very short response to single-agent therapy. In Hodgkin lymphoma, the use of combination chemotherapy results in long-term, disease-free survival for more than 60% of patients. If K.K. were to receive single-agent therapy, her disease would not be cured. Combination chemotherapy is recommended to provide her with the best chance for long-term, disease-free survival.

Combination chemotherapy provides broader coverage against resistant cell lines within the heterogeneous tumor mass. Several principles provide the basis for selecting the agents to be included in a chemotherapy regimen:

- Agents with demonstrable single-agent activity against the specific type of tumor should be used in combination therapy.
- Agents in the regimen should have different mechanisms of action.
- Agents should not have overlapping toxicities so that the severity and duration of acute and chronic toxicities are minimized.
- Agents in the regimen should be used in their optimal dose and schedule.

Subsequent chapters will provide examples of commonly used systemic regimens in the treatment of hematologic and solid tumor malignancies.

Primary treatment is the first-line therapy, and in certain tumor types may be referred to as induction therapy. Choice of primary treatment is governed by observations made from clinical trials that demonstrate that a given regimen has the highest known activity against the tumor. These regimens may include chemotherapy, targeted agents, endocrine agents, or biologic response modifiers. Second-line treatment is administered after the tumor has become refractory to primary therapy or if the patient is unable to tolerate first-line therapy. Systemic therapy is frequently used in different ways during the course of an individual's malignancy. Primary treatment can be either curative or palliative, depending on the specific type of tumor (Table 93-6).[48] After primary therapy, patients may receive additional treatment in an attempt to further eradicate residual disease and improve their chances for long-term survival. This treatment may be termed consolidation, intensification, or maintenance therapy. See subsequent chapters for specific discussion of the use of primary, consolidation, or maintenance therapy in the treatment of hematologic and solid tumor malignancies.

Adjuvant Therapy

CASE 93-8

QUESTION 1: F.R., a 58-year-old woman with no other medical problems, recently underwent surgical resection for stage III ovarian cancer. She has been told that she currently has no evidence of cancer;

however, she also is told that she should now receive 6 months of chemotherapy. Why would chemotherapy be recommended now when she has no detectable disease?

Micrometastases or residual disease may still be present in some patients after primary treatment. These patients have a high probability of disease recurrence, even though the primary treatment may have successfully removed all visual evidence of the primary tumor. To eradicate any undetectable tumor in these patients, systemic therapy after initial curative surgery (or radiation therapy) may be recommended. Systemic treatment administered after primary therapy (in the case of F.R., primary therapy was surgery) is referred to as adjuvant therapy. Because the tumor burden is relatively low at this time, adjuvant therapy should immediately follow primary therapy. For adjuvant therapy to provide benefit, the risk of tumor recurrence must be high, and effective agents must be available to eradicate the tumor. Adjuvant therapy is considered standard of care for some stages of breast, lung, and colorectal cancer, but it also has benefited selected patients with ovarian cancer, Ewing sarcoma, Wilms tumor, and other malignancies (Table 93-7).[48] The duration of administration of adjuvant therapy varies depending on the type of cancer being treated and the drugs being used, but is typically several weeks to months in duration. See subsequent chapters for specific discussion of the use of adjuvant therapy in solid tumor malignancies. F.R. will receive adjuvant chemotherapy with six to eight cycles of carboplatin and paclitaxel.

Table 93-7

Neoplasms for Which Adjuvant Systemic Therapy is Indicated After Primary Treatment

Anaplastic astrocytoma
Breast cancer
Colorectal cancer
Gastric cancer
Melanoma
Non-small-cell lung cancer
Osteogenic sarcoma
Ovarian cancer

Reprinted from DeVita VT Jr, Chu E. Principles of medical oncology: basic principles. In: DeVita VT Jr et al, eds. *DeVita, Hellman, and Rosenberg's Cancer: Principles & Practice of Oncology*. 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008:339, with permission.

Because it is difficult to detect micrometastases or residual disease, it is a challenge to determine which patients should receive adjuvant therapy. To help with these decisions, clinicians frequently consider histologic and cytogenetic characteristics of the primary tumor that are associated with high risk of relapse.

Neoadjuvant Therapy

Neoadjuvant therapy is given before the primary treatment (typically surgery or radiation) in patients who present with locally advanced tumors (e.g., large tumors or those that are impinging on surrounding vital structures) that are unlikely to be cured with primary therapy alone. The objective of neoadjuvant therapy is to reduce the tumor mass, thereby increasing the likelihood of eradication by subsequent surgery or radiation. Neoadjuvant therapy also can lessen the amount of radical surgery the patient needs, which can preserve cosmetic appearance and function of the surrounding normal tissues. The tumor can be resistant to neoadjuvant therapy and continue to grow, however, making surgery or radiation even more difficult. Patients may also experience toxicities with neoadjuvant therapy that may delay surgery or impair postsurgical healing. Locally advanced tumors in which neoadjuvant therapy has been shown to improve survival rates include non-small-cell lung cancer, breast cancer, sarcomas, esophageal cancers, laryngeal cancer, bladder cancer, and osteogenic sarcoma (Table 93-8).[48] See subsequent chapters for specific discussion of the use of neoadjuvant therapy in solid tumors.

CASE 93-9

QUESTION 1: H.P. is a 57-year-old man who is currently undergoing a staging workup for a presumed diagnosis of metastatic adenocarcinoma of the lung. He has heard that cytotoxic “chemotherapy is the only thing available to treat metastatic cancer.” What other agents are being used to treat cancer besides those that are considered cytotoxic?

TARGETED THERAPY

By understanding the mechanisms by which cancer cells exhibit unregulated growth and immortality and possess the ability to invade tissues and metastasize, it has been possible to design drugs that inhibit these processes.

Monoclonal Antibodies

Directed at specific receptors associated with cancer, monoclonal antibodies block ligands from binding to their targets. Unlike traditional chemotherapy, monoclonal antibodies selectively target receptors or their ligands known to potentiate cancer pathways, and as a result, minimize toxicity to noncancer cells. Table 93-9 provides a list of monoclonal antibodies currently approved by the US Food and Drug Administration to treat malignancy.[35]

Tyrosine Kinase Inhibitors

Tyrosine kinase inhibitors (TKIs) are small molecules that directly inhibit tyrosine kinase activation by competing with ATP for binding to the intracellular tyrosine kinase domain. Advantages of these inhibitors include inhibiting cells that may not overexpress the receptor on their surface or have mutated forms of the receptor that result in its activation and direct inhibition of cell signaling. Even though most TKIs are designed to inhibit a single target, they often have inhibitory properties for additional molecules, which could affect an internal cascade of biologic activity resulting in antitumor activity and toxicity.

Table 93-8

Neoplasms for Which Neoadjuvant Systemic Therapy is Indicated for Locally Advanced Disease

Anal cancer
Bladder cancer
Breast cancer
Cervical cancer
Gastroesophageal cancer
Lung cancer
Head and neck cancer
Ovarian cancer
Osteogenic sarcoma
Pancreatic cancer

Reprinted with permission from DeVita VT, Jr, Chu E. Principles of medical oncology: basic principles. In: DeVita VT, Jr et al, eds. DeVita, Hellman, and Rosenberg's Cancer: Principles & Practice of Oncology. 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008:338.

This class of drug is taken orally. Due to varying pharmacokinetics, specific instructions on self-administration should be provided to patients (i.e., take on an empty stomach, take with a full meal). Additionally, many TKIs are substrates, inhibitors, and inducers of CYP P450 enzymes. Attention to potential drug interaction is crucial to safe medication use.

Table 93-10 provides the TKIs currently approved by the US Food and Drug Administration to treat malignancies.[35]

Other Targeted Therapy

Because more information is learned regarding signal transduction pathways and cellular growth and proliferation, more drugs are being developed that target these key molecules. Histone deacetylase (HDAC) inhibitors, mammalian target of rapamycin (mTOR) inhibitors, and proteasome inhibitors are examples of drugs that have novel mechanism(s) of action. Table 93-11 lists these and other targeted agents currently approved by the US Food and Drug Administration to treat malignancies.[35]

Combination Therapy with Targeted Agents

The optimal activity of adding targeted agents to cytotoxic chemotherapy is difficult to predict. Knowledge about how to combine targeted agents with chemotherapy is limited, although clinical investigations are ongoing. See subsequent chapters for specific discussion of the use of targeted therapy with chemotherapy in solid tumor and hematologic malignancies.

ENDOCRINE THERAPY

Endocrine therapy can be used to treat several common cancers, including breast, prostate, and endometrial cancers, which arise from hormone-sensitive tissues (Table 93-12). These tumors grow in response to endogenous hormones that trigger growth signals. Current endocrine therapies inhibit tumor growth by blocking hormone receptors or by eliminating endogenous hormone feeding the tumor. Not all tumors arising from hormone-sensitive tissues respond to endocrine manipulation. Lack of response may be associated with hormone-resistant tumor cells or inadequate suppression of the endogenous feeding hormones.[49]

IMMUNOTHERAPY

Immune therapy is comprised of substances that stimulate the body's immune system to identify circulating tumor cells. Some agents target certain cells of the immune system; other agents are more nonspecific.[34] An individual's immune system plays a crucial role in developing or eradicating cancer. Normally, an intact immune system can protect the host against malignant cells and infectious pathogens, but current evidence shows that individuals with "weakened" immune systems are at an increased risk of developing cancer. Immunotherapy can include vaccines, cytokines, and checkpoint inhibitors.

Table 93-9

Monoclonal Antibodies

Class[a]	Agent (Trade Name)	Mechanism of Action	Notable Toxicities
Anti-CD19, Anti-CD3	Blinatumomab (Blincyto)	Binds to CD19 on B cells and CD3 on T cells; causes formation of cytolytic synapses between B and T cells	Neurotoxicity; infection; tremor; fever; edema, rash; nausea, diarrhea, constipation; cytokine release syndrome
Anti-CD20	Obinutuzumab (Gazyva)	Binds to CD20 on B cells; induces cell death via ADCC, CDC, and antibody-dependent cellular phagocytosis	Myelosuppression; hepatic and renal dysfunction; electrolyte abnormalities; infection; infusion reaction
	Ofatumumab (Arzerra)	Binds to CD20 on B cells at different binding sites than rituximab; induces cell death via ADCC and CDC	Cough; diarrhea, nausea; fatigue; myelosuppression; hypersensitivity reaction, pyrexia; rash; infection
	Rituximab (Rituxan)	Binds to CD20 on B cells; induces cell death via ADCC and CDC	Hypersensitivity reaction; myelosuppression; infection; tumor lysis syndrome
Anti-CD20 Radiation	Ibritumomab tiuxetan (Zevalin)	Yttrium-90 (Y-90) linked to rituximab; binds to CD20 on B cells and releases radiation (β particles); induces cell damage via free radicals	Infusion-related reaction; chills, nausea; fatigue; myelosuppression; see notable toxicities for rituximab
	Tositumomab (Bexxar)	Iodine-131 linked to rituximab; binds to CD20 on B cells and	Infusion-related reaction; nausea; myelosuppression,

		releases radiation; induces cell death via ADCC and CDC	infection; hypothyroidism; see notable toxicities for rituximab

Anti-CD30	Brentuximab vedotin (Adcetris)	Three-component antibody drug conjugate; binds to cells expressing CD30 and is internalized; monomethyl auristatin E is then released which disrupts the microtubule network	Myelosuppression; peripheral neuropathy; fatigue; nausea, vomiting, diarrhea; fever; rash; upper respiratory infection
Anti-CD52	Alemtuzumab (Campath)	Binds to CD52, leading to lysis of CD52-positive leukemic cells	Hypersensitivity reaction; myelosuppression, opportunistic infection, fever; nausea, rash
Anti-EGFR	Cetuximab (Erbitux)	Binds to EGFR, preventing activation and inhibiting cell proliferation	Papulopustular rash; hypersensitivity reaction; fatigue; nausea, vomiting, stomatitis; hypomagnesemia
	Panitumumab (Vectibix)	Binds to EGFR with higher affinity than cetuximab, preventing activation and inhibiting cell proliferation	Papulopustular rash, pruritus; fatigue; hypersensitivity reactions; abdominal pain, nausea, diarrhea; hypomagnesemia; paronychia
Anti-HER2	Ado-Trastuzumab emtansine (Kadcyla)	HER2-antibody drug conjugate of trastuzumab and microtubule inhibitor DM1; binds to HER2 inducing cell cycle arrest and cell death	Myelosuppression, nausea, constipation, diarrhea; fatigue, peripheral neuropathy; hypokalemia, fever
	Pertuzumab (Perjeta)	Binds to HER2, inhibiting HER2 dimerization and downstream signaling, halting cell growth	Myelosuppression; cardiomyopathy; fatigue, alopecia; nausea, vomiting, diarrhea
	Trastuzumab (Herceptin)	Binds to HER2; induces cell death via ADCC	Cardiomyopathy; nausea, vomiting, diarrhea; infusion-related reaction
Anti-VEGF	Bevacizumab (Avastin)	Binds to and inhibits VEGF ligand interaction with receptors, blocking angiogenesis	Hypertension; bleeding, thrombosis; gastrointestinal perforation; impaired wound healing; proteinuria
	Ramucirumab (Cyramza)	Binds to and inhibits VEGF2 ligand interaction with receptors (VEGF-A, VEGF-C, VEGF-D), blocking angiogenesis	Hypertension; proteinuria; infusion-related reaction; bleeding; thrombosis; gastrointestinal perforation
Immune Checkpoint Inhibitors	Ipilimumab (Yervoy)	Enhances T-cell activation and proliferation by inhibiting CTLA-4; restoring antitumor immune response	Fatigue; nausea, anorexia, diarrhea, colitis; pruritus, rash; hepatic dysfunction; hypophysitis
	Nivolumab (Opdivo)	Enhances T-cell activation and proliferation by inhibiting PD-1	Rash, pruritus; nausea, constipation, diarrhea; fatigue;

		activity, which is a negative regulator of T-cell pathways; restores antitumor immune response	electrolyte abnormalities; hepatic dysfunction; musculoskeletal pain; cough, pneumonitis
	Pembrolizumab (Keytruda)		Fatigue; pruritus, rash; electrolyte abnormalities; hepatic dysfunction; nausea, constipation, diarrhea; arthralgia; cough, pneumonitis
Other	Dinutuximab (Unituxin)	Cell lysis of GD-2-expressing neuroblastoma cells via ADCC and CDC	Myelosuppression; urticaria; diarrhea, nausea, vomiting; hepatotoxicity; fever; capillary leak syndrome; infusion-related reaction; peripheral neuropathy

[a] All monoclonal antibodies are administered intravenously, IV.

ADCC, antibody-dependent cellular toxicity; CDC, complement-dependent cytotoxicity; CTLA-4, cytotoxic T-lymphocyte-associated antigen-4; EGFR, epidermal growth factor receptor; HER, human epidermal growth factor receptor; PD-1, programmed cell death-1; VEGF, vascular endothelial growth factor.

Sipuleucel-T (Provenge) is a cancer vaccine approved for patients with metastatic prostate cancer that is resistant to prior endocrine therapy.[50] The immune system is stimulated to recognize the patient's own cancer cells. The cytokines, interferon-α and interleukin 2, were the first immune-modulating therapies available. They nonspecifically stimulate B- and T-cell proliferation and differentiation along with activity on other immune functions.[51–56] Immune checkpoint inhibitors release the brakes on the immune system, allowing it to identify and kill cancer cells better.[34]

If H.P. is in fact diagnosed with stage IV adenocarcinoma of the lung, he may receive other agents besides chemotherapy during the course of treatment for his disease. For specific discussion of which noncytotoxic agents H.P may receive, refer to Chapter 98, Lung Cancer.

Table 93-10

Tyrosine Kinase Inhibitors

Class[a]	**Agent (Trade Name)**	**Mechanism of Action**	**Notable Toxicities**
ALK inhibitor		Inhibits ALK thereby reducing tumor cell proliferation in cells expressing ALK fusion protein; also inhibits ROS1 kinase	Myelosuppression, visual disturbances; liver enzyme elevations; diarrhea, nausea, vomiting; fatigue
	Ceritinib (Zykadia)	Also inhibits IGF-1R, insulin receptor kinases	Also: increased creatinine; hyperglycemia
	Crizotinib (Xalkori)		Also: dysgeusia; edema; bradycardia

BCR-ABL inhibitor		Inhibits BCR-ABL kinase, c-KIT, and PDGFR kinases	Myelosuppression; nausea, vomiting, diarrhea; fatigue; dermatologic toxicity
	Bosutinib (Bosulif)	Includes activity against most imatinib-resistant BCR-ABL mutations and SRC kinases	Also: electrolyte disturbances; liver enzyme elevations; fever; cough, dyspnea
	Dasatinib (Sprycel)	Inhibits most imatinib-resistant BCR-ABL mutation kinases and SRC kinases	Also: headache; fluid retention, pleural effusion
	Imatinib mesylate (Gleevec)		Also: fluid retention; headache; hepatic toxicity; musculoskeletal pain
	Nilotinib (Tasigna)	Inhibits most imatinib-resistant BCR-ABL mutation kinases	Also: musculoskeletal pain; hepatic toxicity; hyperglycemia; QT prolongation
	Ponatinib (Iclusig)	Inhibits most imatinib-resistant BCR-ABL mutation kinases and VEGFR, SRC RET, and FLT3 kinases	Also: hypertension; edema, arterial ischemia; headache; arthralgias; constipation; hepatic dysfunction; dyspnea, pleural effusion
BTK inhibitor		Irreversibly inhibits the BTK of the B-cell receptor signaling pathway	Myelosuppression; nausea, diarrhea; fatigue, edema, fever; dermatologic toxicity; musculoskeletal pain; tumor lysis syndrome
	Ibrutinib (Imbruvica)		
EGFR inhibitor		Inhibits EGFR TK; resulting tumor growth inhibition	Rash, dry skin, pruritis; paronychia; diarrhea
	Afatinib (Gilotrif)	Irreversible inhibitor of EGFR as well as HER2 and HER4	Also: stomatitis, decreased appetite
	Erlotinib (Tarceva)	Reversible inhibitor of EGFR	
HER2 inhibitor		Reversibly inhibits HER2 and EGFR TK	Nausea, diarrhea; dermatologic toxicity; myelosuppression; hepatic toxicity; cardiomyopathy, QT prolongation; pulmonary toxicity
	Lapatinib (Tykerb)		
MEK inhibitor		Decreased cell proliferation and increased apoptosis by inhibiting MEK activation, which is a downstream effector of BRAF (mutant)	Cardiomyopathy; acneiform rash; diarrhea; hepatic dysfunction; edema; QT prolongation; hypoalbuminemia
	Trametinib (Mekinist)		
PI3K inhibitor		Inhibits PI3K expressed on B cells	Myelosuppression; nausea, diarrhea, colitis, gastrointestinal perforation; fatigue; hepatic toxicity; pulmonary toxicity
	Idelalisib (Zydelig)		
VEGF inhibitor		Inhibits VEGF receptor tyrosine	Hypertension; diarrhea, nausea,

		kinases thereby blocking angiogenesis and tumor growth	vomiting
	Axitinib (Inlyta)		Also: electrolyte disturbances; creatinine increased; fatigue; myelosuppression; proteinuria
	Cabozantinib (Cometriq)	Also inhibits FLT-3, KIT, MET, RET kinases	Also: liver enzyme elevation; stomatitis, weight loss, anorexia; fatigue; electrolyte disturbances; hand-foot syndrome, hair color changes
	Lenvatinib (Lenvima)	Also inhibits PDGFR, KIT, and RET kinases	Also: palmar-plantar erythrodysesthesia; proteinuria; thrombosis, bleeding; hepatic toxicity; gastrointestinal perforation

	Pazopanib (Votrient)	Also inhibits c-KIT, PDGFR, FGFR kinases	Also: depigmentation of hair and skin; dysgeusia, visual disturbances; muscle spasms; alopecia, rash
	Regorafenib (Stivarga)	Also inhibits PDGFR-α and -β, RET, RAF-1 kinases	Also: mucositis; fatigue; proteinuria; palmar-plantar erythrodysesthesia: rash; dysphonia; fever; myelosuppression; infection
	Sorafenib (Nexavar)	Also inhibits RAF kinases, PDGFR-β, FLT-3, c-KIT, RET kinases	Also: rash, palmar-plantar erythrodysesthesia; myelosuppression
	Sunitinib (Sutent)	Also inhibits PDGFR-α and - FLT-3 kinases	Also: Myelosuppression; prolonged QT interval; palmar-plantar erythrodysesthesia, skin discoloration
	Vandetanib (Caprelsa)	Also inhibits EGFR, RET, SRC kinases	Also: QT prolongation; headache; colitis; hepatic dysfunction; leukopenia; rash, photosensitivity

[a] All tyrosine kinase inhibitors are administered orally, PO.

ALK, anaplastic lymphoma kinase; ROS1, c-ros oncogene 1; IGF-1R, insulin-like growth factor 1 receptor; BCR-ABL, breakpoint cluster region-ABL1 gene fusion gene; KIT, tyrosine-protein kinase kit; PDGFR, platelet-derived growth factor; SRC, steroid receptor coactivator; VEGFR, vascular endothelial growth factor receptor; RET, c-RET oncogene; FLT-3, Fms-like tyrosine kinase 3; BTK, Bruton tyrosine kinase; EGFR, epidermal growth factor receptor; TK, tyrosine kinase; HER2, human epidermal growth factor receptor 2; HER4, human epidermal growth factor receptor 4; MEK, mitogen-activated protein kinase (MAPK)/extracellular signal-regulated kinase (ERK) kinase; BRAF, proto-oncogene b-Raf; PI3K, phosphatidylinositol 3-kinase; MET, proto-oncogene c-Met; FGFR, fibroblast growth factor receptor; RAF, MAPK 3 kinase

Administration

Systemic

Systemic chemotherapy is most commonly administered by the intravenous route, either as a bolus injection (generally <15 minutes), short infusion (15 minutes to several hours), or as a continuous infusion (lasting 24 hours to several weeks). Some chemotherapy can also be administered orally, intramuscularly, or subcutaneously.

Targeted agents are most commonly administered intravenously or orally. Monoclonal antibodies are primarily administered intravenously, whereas small-molecule TKIs are primarily administered by mouth. Endocrine agents are primarily administered orally or subcutaneously.

Although chemotherapy was initially developed for systemic use, techniques have been developed to administer agents directly to specific sites of the body affected by the tumor (Table 93-13). Regionally or locally administered chemotherapy allows for high concentrations of drug at the tumor site while reducing systemic exposure and subsequent toxicity. However, a potential disadvantage is that distant micrometastases may not be exposed to chemotherapy, allowing continued growth of tumor cells.

Assessing Response to Therapy

CASE 93-10

QUESTION 1: G.K. is a 67-year-old woman who was recently diagnosed with metastatic breast cancer. Her symptoms include widespread pain, anorexia, and fatigue. She has received two cycles of treatment with a combination chemotherapy regimen. A recent CT scan of her abdomen showed marked shrinkage at several tumor sites and her pain has decreased. How long should she continue to receive this chemotherapy?

An important step in the treatment process is assessing response to treatment. This assessment should include evaluation of efficacy as well as toxicity, including impact on the patient's overall quality of life. Re-evaluation should occur at regularly scheduled intervals and include physical examination, laboratory tests, and repeat diagnostic imaging.

Response Evaluation Criteria in Solid Tumors (RECIST) was introduced in 2000 to unify response assessment criteria, define how to choose evaluable tumors, and enable the use of new imaging technologies (spiral CT and MRI). The World Health Organization, National Cancer Institute, and European Organization for Research and Treatment of Cancer have adopted RECIST criteria as the standard for evaluating tumor response (Table 93-14).[57]

Several standardized toxicity grading scales are available to assess toxicity associated with chemotherapy. However, the National Cancer Institute Common Toxicity Criteria for Adverse Events is the most commonly used.[31,58] Toxic effects of systemic therapy will be further discussed in Chapter 94, Adverse Effects of

Chemotherapy and Targeted Agents.

Because toxicities associated with systemic therapy are potentially severe, it is important to evaluate the risks and benefits. The benefits of a treatment regimen should outweigh the negative effects it has on the physical, mental, and social well-being of the patient. To monitor a patient's quality of life, several comprehensive assessment tools have been developed.[59] In addition, other clinical benefits (e.g., reduced pain, decreased use of analgesics, weight gain, improved performance status) have been recognized by the US Food and Drug Administration as acceptable criteria for measuring quality of life. These criteria are also considered when evaluating new agents for approval.

G.K. should continue to receive the same therapy as long as her tumor is responding and she does not experience intolerable or life-threatening treatment-related toxicities. For some cancers, continued therapy after a certain number of cycles is not associated with further benefit because toxicity becomes an overriding issue.

Tumor Markers

Tumor markers are substances found in tumor tissue or released from tumor into the blood or other body fluids (e.g., urine).[34] However, not all cancers have relevant tumor markers. The ideal tumor marker should be produced and released primarily by cancer cells (or by other tissues in response to tumor) at levels proportional to the tumor mass. Surgical removal of the tumor, radiation therapy, or therapeutic response to systemic therapy should result in a reduction in the level of the marker. In addition, the ideal tumor marker should be measurable at very low levels, allowing for detection of tumor at lower volumes than conventional diagnostic imaging permits.[60] Tumor markers may therefore be used to monitor patients in remission and to detect recurrent disease. Unfortunately, few tumor markers fulfill these criteria sufficiently to be clinically useful as the sole screening or diagnostic test. Most tumor markers lack specificity for tumor and may be elevated due to other causes. Table 93-15 lists some of the common tumor markers used in practice.

Table 93-11

Other Targeted and Miscellaneous Agents

Class	Agent (Trade Name)	Mechanism of Action	Route of Administration	Notable Toxicities
HDAC inhibitors		Inhibits HDAC resulting in accumulation of acetyl groups, cell cycle arrest,		Nausea, vomiting; fatigue; myelosuppression; fever; peripheral edema; EKG

		and apoptosis		changes
	Belinostat (Beleodaq)		IV	
	Panobinostat (Farydak)		PO	Also: diarrhea; electrolyte abnormalities; increased creatinine; fever
	Romidepsin (Istodax)		IV	Also: anorexia, dysgeusia; pruritis, dermatitis; infection
	Vorinostat (Zolinza)		PO	Also: diarrhea, anorexia, weight loss, dysgeusia; proteinuria; pruritis, alopecia
Proteasome inhibitor		Inhibits proteasomes, enzymes that regulate protein homeostasis within cells		Nausea, diarrhea, constipation; peripheral neuropathy; headache, fatigue, fever; myelosuppression; herpes zoster reactivation
	Bortezomib (Velcade)		IV and SC	
	Carfilzomib (Kyprolis)		IV	Also: edema, dyspnea; cardiac toxicity; hypersensitivity reactions
mTOR inhibitors		Inhibits mTOR kinase, VEGFR		Fatigue, nausea, anorexia; dermatologic toxicity; hyperlipidemia, hyperglycemia, electrolyte abnormalities; stomatitis; myelosuppression, infection; pneumonitis
	Everolimus (Afinitor)		PO	
	Temsirolimus (Torisel)		IV	Also: gastrointestinal perforation
Immunomodulating Agents		Immunomodulatory and angiogenic effects		Fatigue; teratogenic potential; thromboembolism; arthralgias
	Lenalidomide (Revlimid)	Inhibits secretion of proinflammatory cytokines; induces cell cycle arrest and apoptosis in myeloma cells	PO	Also: thrombocytopenia, neutropenia, pruritus; rash; diarrhea, pyrexia; dizziness
	Pomalidomide (Pomalyst)	Induces cell cycle arrest and apoptosis in myeloma cells; enhances T-cell- and NK-cell-mediated cytotoxicity	PO	Also: rash; peripheral edema; constipation, nausea, diarrhea; myelosuppression; muscle spasms; dyspnea, renal dysfunction
	Thalidomide (Thalomid)		PO	Also: bradycardia; dizziness; somnolence; neutropenia, peripheral neuropathy
BRAF inhibitor		Blocks cellular proliferation of mutated BRAF		Dermatologic toxicity; nausea, diarrhea; edema; headache; hepatic dysfunction; fever, chills; secondary skin cancer

	Dabrafenib (Tafinlar)		PO	Also: electrolyte abnormalities, hyperglycemia; myelosuppression
	Vemurafenib (Zelboraf)		PO	Also: fatigue; arthralgias; anorexia
Other				
CDK inhibitor	Palbociclib (Ibrance)	Reversibly inhibits CDK	PO	Myelosuppression, infection, fatigue; nausea, vomiting, diarrhea; stomatitis, alopecia; thrombosis
Hedgehog inhibitor	Vismodegib (Erivedge)	Selectively binds and inhibits the transmembrane protein in Hedgehog signal transduction pathway; inhibits unrestricted proliferation of skin basal cells	PO	Fatigue; alopecia; anorexia, nausea, diarrhea, constipation; muscle spasms; arthralgias
IL-2 receptor inhibitor	Denileukin diftitox (Ontak)	Fusion protein containing diphtheria toxin and IL-2 segments; directs cytocidal action of diphtheria toxin to IL-2 receptor-expressing cells leading to inhibition of protein synthesis, cell death	IV	Hypersensitivity reaction; nausea, vomiting, diarrhea; fatigue; rash; fever, rigors, capillary leak syndrome; peripheral edema
PARP inhibitor	Olaparib (Lynparza)	Inhibits the PARP enzyme, inducing synthetic lethiality in BRCA deficient cells	PO	Nausea, vomiting, fatigue; myelosuppression; musculoskeletal pain; thrombosis; upper respiratory infection; interstitial lung disease; secondary malignancy
VEGF inhibitor	Ziv-Aflibercept (Zaltrap)	Fusion protein comprised of VEGF receptor binding domains, acting as a decoy receptor for VEGF, inhibiting angiogenesis	IV	Fatigue, diarrhea, stomatitis; myelosuppression; hypertension, proteinuria; bleeding, impaired wound healing; thrombosis; gastrointestinal perforation

IV, intravenous; PO, oral; SC, subcutaneous; HDAC, histone deacetylase; mTOR, mammalian target of rapamycin; VEGF, vascular endothelial growth factor; NK, natural killer; BRAF, proto-oncogene b-Raf; CDK, cyclin-dependent kinase; IL-2, interleukin 2; PARP, poly ADP-ribose polymerase.

Table 93-12

Endocrine Therapies

Class	Agent	Mechanism of Action	Route of Administration	Notable Toxicities

Androgens		Synthetic derivative of testosterone; suppresses GnRH, LH, FSH by a negative feedback system		Deepening voice, alopecia, hirsutism, facial or truncal acne, fluid retention, menstrual irregularities, cholestatic jaundice
	Fluoxymesterone (Androxy)		PO	
Antiandrogens				Hot flashes; breast tenderness; hepatic dysfunction, diarrhea; fatigue; edema; hypertension; arthralgia
	Abiraterone (Zytiga)	Inhibits formation of testosterone precursors (DHEA, androstenedione); selectively inhibits CYP17	PO	Also: hypertriglyceridemia; electrolyte abnormalities
	Bicalutamide (Casodex)	Nonsteroidal androgen receptor inhibitor	PO	Also: gynecomastia; back pain; constipation; infection
	Enzalutamide (Xtandi)	Inhibits androgen receptor translocation, leading to cellular apoptosis	PO	Also: constipation; neutropenia
	Flutamide (Eulexin)	Inhibits androgen uptake and binding in tissue; nonsteroidal	PO	Also: galactorrhea; decreased libido; impotence; rectal hemorrhage
	Nilutamide (Nilandron)	Nonsteroidal androgen receptor inhibitor	PO	Also: insomnia; headache; constipation; flu-like syndrome; decreased libido
Antiestrogens		Competitive binding of estrogen receptors produces downregulation of estrogen receptors		Liver enzyme elevation; hot flashes; myalgia, arthralgia; nausea, vomiting; thromboembolism
	Fulvestrant (Faslodex)		IM	
	Tamoxifen (Nolvadex, Soltamox)		PO	Also: nausea, vomiting; edema, endometrial cancer

Aromatase inhibitors		Inhibits aromatase preventing androgen conversion to estrogen		Hot flashes; nausea; fatigue, insomnia; increased risk of bone fractures, arthralgia

	Anastrozole (Arimidex)		PO	
	Exemestane (Aromasin)		PO	
	Letrozole (Femara)		PO	Also: hypercholesterolemia
Estrogens		Suppresses androgen synthesis, as well as secretions of gonadotropins, FSH and LH via negative feedback system		Nausea, vomiting, fluid retention, hot flashes, anorexia, thromboembolism, hepatic dysfunction
	Ethinyl estradiol (Estradiol)		PO	
	Conjugated estrogens (Premarin)		PO	Also: headache
GnRH analogs (LHRH agonists)		Downregulates GnRH receptor on the pituitary gland, decreasing secretion of FSH and LH		Amenorrhea, hot flashes, sexual dysfunction; nausea, edema; tumor flare; injection-site reaction; osteoporosis
	Goserelin (Zoladex)		SC	Also: headache, emotional lability, cystitis, vaginitis
	Histrelin (Vantas)		SC	
	Leuprolide (Lupron, Eligard)		IM, SC	Also: vaginitis
	Triptorelin (Trelstar)		IM	
GnRH antagonists		Binds to GHRH receptors on the pituitary gland, blocking secretion of FSH and LH		Hot flashes; hepatic toxicity; injection-site reaction
	Degarelix (Firmagon)		SC	
Progestins		Promotes differentiation and maintenance of endometrial tissue		Weight gain, edema; hot flashes, vaginal bleeding; thrombosis
	Medroxyprogesterone (Provera)		PO	Also: emotional lability
	Megestrol acetate (Megace)	Also: may suppress LH and enhance estrogen metabolism	PO	

CYP, cytochrome; DHEA, dehydroepianderosterone; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; IM, intramuscular; LH, luteinizing hormone; LHRH, luteinizing hormone-releasing hormone; PO, oral; SC, subcutaneous.

Table 93-13

Regional or Local Routes of Chemotherapy Administration

Route of Administration	Cancer Managed With Alternative Route
Intrathecal or intraventricular	Leukemia, lymphoma

Intravesicular	Bladder
Intraperitoneal	Ovarian
Intrapleural	Malignant pleural effusions
Intra-arterial	Melanoma, sarcoma
Hepatic artery	Liver metastases
Chemoembolization (intra-arterial or intravenous)	Colon, rectal, carcinoid, liver metastases

Table 93-14

Response Criteria for Evaluating Effects of Chemotherapy of Target Lesion (RECIST version 1.1)

Complete Response

Disappearance of all target lesions. Any pathologic lymph nodes (whether target or nontarget) must have reduction in short axis to <10 mm

Partial Response

At least a 30% decrease in the sum of diameters of target lesions, taking as reference the baseline sum diameters

Progressive Disease

At least a 20% increase in the sum of diameters of target lesions, taking as reference the smallest sum on study (this includes the baseline sum if that is the smallest on study). In addition to the relative increase of 20%, the sum must also demonstrate an absolute increase of at least 5 mm. The appearance of one or more new lesions is also considered progression

Stable Disease

Neither sufficient shrinkage to qualify for partial response nor sufficient increase to qualify for progressive disease, taking as reference the smallest sum diameters while on study

HANDLING OF CYTOTOXIC DRUGS

Impact on the Pharmacy

CASE 93-11

QUESTION 1: The administrator of an outpatient care clinic recently announced that two medical oncologists will be joining the staff. Previously, patients were referred to outside oncologists and no cytotoxic drugs were prepared or administered at this clinic. What implications will the addition of these physicians have on the pharmacy department?

Addition of cancer treatment to institutional services will affect three areas of the pharmacy department: budget, policies and procedures for safe drug handling and disposal, and the staff education program. The pharmacy department will need to increase its budget to accommodate additional personnel and purchase new equipment, supplies, supportive care medicines, and chemotherapy agents. To estimate the projected budget increase, pharmacy leadership should meet with the oncologists to discuss anticipated volume of chemotherapy orders including systemic therapy and supportive care medicines (e.g., antiemetic therapy, analgesics, growth factors) likely to be prescribed. All new systemic therapy agents and supportive care medicines should be added to the institutional formulary. In addition, projected use of investigational agents, clinical pharmacy services needed, and any plans to develop an ambulatory infusion program should be determined. Institutional policies and procedures to ensure safe handling of chemotherapy agents must be created. These should be conveyed to all personnel affected through a staff education program because safe handling of chemotherapy agents is critical in decreasing the risk of medication errors and injuries.

Medication Errors

Several chemotherapy-related medication errors resulting in death or permanent disability have been highly publicized. These devastating events have brought significant attention to the entire drug use process in oncology and have identified several factors that appear to contribute to the risk. Use of abbreviations, verbal orders, multiple-day regimens, incorrect references and protocols, and illegible medication orders has contributed to medication errors. Increasing use of computerized prescriber order entry and standardized preprinted orders have helped eliminate many errors. Several groups have responded to the problem by issuing policy recommendations to minimize such errors.[61–66]

Table 93-15

Clinically Useful Tumor Markers

Tumor Markers	Cancers Commonly Associated With Increased Markers
CA-19-9	Pancreatic
CA-15-3, CA-27-29	Breast
α-Fetoprotein (AFP)	Liver, testicular, ovarian
CA-125	Ovarian
Carcinoembryonic antigen (CEA)	Colon, lung
Human chorionic gonadotropin (hCG)	Trophoblastic, testicular
β_2-Microglobulin	Multiple myeloma
Prostate-specific antigen (PSA)	Prostate

Risks

CASE 93-11, QUESTION 2: What are the potential risks of handling cytotoxic drugs? What resources are available to assist the pharmacy director and the pharmacy staff in the development of policies and procedures?

Many of these agents are carcinogenic, teratogenic, or mutagenic in animal models and in humans at therapeutic doses.[66] Danger to healthcare personnel handling such agents results from inherent toxicities of the agents and the extent (i.e., amount and length of time) to which the workers are exposed during drug handling.[66] Various studies have attempted to assess the effect of occupational exposure to hazardous drugs on healthcare workers. These studies measured urine mutagenicity, chromosomal damage, blood concentrations, and the level of contamination that occurs in the work areas used for drug preparation and administration.[66–68] These studies indicate urine mutagenicity and chromosomal damage in workers may be a direct result of cytotoxic exposure. Other reports have correlated reproductive risks (e.g., infertility or increased risk of miscarriage) and birth defects in pregnant workers handling cytotoxic drugs.[67,69] Findings from these reports together with the toxicities observed in patients receiving therapeutic doses led the American Society of Health-System Pharmacists to conclude that healthcare workers exposed to hazardous drugs may be absorbing or inhaling these drugs and may be at risk for adverse outcomes.[66]

In response to concerns regarding occupational exposure to hazardous drugs, several groups have published guidelines for the safe handling of these agents in the workplace (i.e., storage, preparation, administration, and disposal).[66,68] These guidelines will be helpful to the pharmacy department when developing policies and procedures.

Policies and Procedures

CASE 93-11, QUESTION 3: What specific policies and procedures are necessary? What other departments should be consulted during the development and implementation of the handling guidelines?

Policies must be developed that address the entire scope of potential occupational exposures within the workplace. These policies should include (a) a worker's "right to know" regarding potential hazards; (b) education and training for workers involved with hazardous drug handling; (c) quality assurance to monitor adherence to safe handling procedures; and (d) guidelines for workers who are attempting to conceive a child, become pregnant, or are nursing.

Specific procedures that outline appropriate handling of hazardous agents during all aspects of institutional storage, use, and disposal should be developed. These procedures should address appropriate (a) storage in the receiving and storeroom areas, (b) preparation and administration of parenteral formulations, (c) manipulation and dispensing of oral and topical formulations, (d) cleanup of spills, (e) management of acute exposures, and (f) disposal of hazardous agents and supplies used to prepare and dispense chemotherapy. If the oncology program includes ambulatory infusion or home-care components, procedures should also be developed for appropriate handling and disposal of these products in the home. Handling of oral chemotherapy and biotherapy must also be specifically addressed. Policies should include processes for cleaning of tools and nondisposable items used to dispense oral cytotoxic agents to minimize contamination with other drugs.[70]

Other departments may be affected by these guidelines including medical staff, nursing, environmental services staff (in the cleanup of spills and equipment), maintenance (upkeep of equipment), and the receiving area (where cytotoxic drugs may be received from suppliers). The institutional safety office and legal staff also should be consulted to help devise the policies and procedures.

Necessary Equipment and Supplies

CASE 93-11, QUESTION 4: What equipment and supplies are necessary for handling hazardous drugs?

Proper equipment and supplies can minimize occupational exposure in the healthcare workplace by protecting both the worker and the environment. All handling guidelines recommend that manipulations (e.g., reconstitution, admixing) of hazardous drugs be done in a class II biologic safety cabinet (BSC) to provide maximal protection for the worker and the work environment. Workers also should wear gloves (one or two pairs), protective boot covers, hair cover, mask, and a disposable gown of lint-free, low-permeability fabric with long sleeves, knit cuffs, and back closure. In addition, only syringes and intravenous sets with threaded Luer lock connections should be used. Final products (e.g., syringes, intravenous bags or bottles) should be placed in sealable containers such as zipper-closure plastic bags to prevent accidental spillage and clearly labeled as a hazardous drug. The United States Pharmacopeia dictates guidelines for compounding sterile products including appropriate facilities for preparation.[71]

Disposal of hazardous waste requires specific receptacles, which should be placed in all areas where workers handle these drugs. Disposal of these agents should follow institutional, state, and local regulations. Materials for the cleanup of spills (e.g., absorbent material, plastic bags or containers, protective garments) also must be available in all areas where hazardous drugs are stored, prepared, or administered.

Adverse Effects of Chemotherapy and Targeted Agents

Amy Hatfield Seung and Emily Mackler

	CORE PRINCIPLES	CHAPTER CASES
1	Myelosuppression is one of the most common toxicities of cytotoxic anticancer therapy. Cytotoxic therapy may affect any one or all of the bone marrow cell lines including erythrocytes, neutrophils, and platelets. Complications from anemia, neutropenia, and thrombocytopenia can cause significant morbidity and mortality, including complications from bleeding and infections. Prophylactic administration of growth factors may protect against the myelosuppressive effects of chemotherapy.	**Case 94-1 (Questions 1–4)**
2	The upper and lower gastrointestinal (GI) tract is highly susceptible to cytotoxic chemotherapy, and toxicities can include nausea and vomiting, mucositis, xerostomia, constipation, and diarrhea. Efficacy of preventive strategies is limited; thus, supportive treatment is a foundation for managing adverse effects in patients.	**Case 94-2 (Questions 1–3), Case 94-3 (Question 1)**
3	Dermatologic toxicities from anticancer therapies include alopecia, nail changes, hyperpigmentation, radiation sensitivities, hand-foot syndrome, dry skin, and papular–pustular (acneiform) rash. Most of the toxicities are cosmetic and resolve upon discontinuation of the agent. Onset and duration of dermatologic toxicities depend on the causative agent. Treatment is supportive.	**Case 94-4 (Questions 1–4), Tables 94-1 and 94-2**
4	Extravasation is the unintended infiltration of an agent into the tissue area surrounding the vein during an infusion. Several anticancer agents demonstrate vesicant properties that can cause tissue necrosis and permanent damage to the extravasated area. Cases of extravasation require emergency treatment that is agent-specific, including elevation of the extremity, extraction of the agent, hot or cold treatment, and potential antidotes.	**Case 94-4 (Questions 5–7), Tables 94-3–94-5**
5	Many anticancer therapies are associated with immunoglobulin-E-mediated hypersensitivity reactions. Monoclonal antibodies including rituximab, trastuzumab, cetuximab, and ofatumumab are among some of the agents most commonly associated with reactions. Reactions commonly occur with the first dose, and they may be minimized with premedications such as acetaminophen, diphenhydramine, and corticosteroids.	**Case 94-5 (Question 1), Tables 94-6 and 94-7**
6	Multiple types of central nervous system (CNS) toxicity, including encephalopathy, cerebellar toxicity, and peripheral neuropathy, are	**Case 94-6 (Questions 1–4), Table 94-8**

	associated with anticancer agents and differ in presentation between various agents. Most of the symptoms of neurotoxicity are reversible over time, but modifications to regimens including discontinuation of agents or reduction of doses may be necessary.	
7	Cardiomyopathy, arrhythmias, and hypertension are common types of cardiotoxicity observed in patients receiving infusion and oral anticancer therapies. Anthracycline-induced cardiomyopathy is closely linked to a patient's cumulative dose and may be treated with current heart failure medications.	**Case 94-7 (Questions 1–4)**

8	Several anticancer agents carry severe risks of nephrotoxicity and bladder toxicity for which preventive measures are necessary. Cisplatin is one of the most nephrotoxic agents. Preventive strategies for cisplatin nephrotoxicity include normal saline hydration, mannitol, and amifostine, and methotrexate-induced nephrotoxicity may be prevented with alkalinization of the urine and leucovorin rescue. Ifosfamide-induced hemorrhagic cystitis may be prevented with concomitant use of mesna.	**Case 94-8 (Questions 1, 2), Case 94-9 (Questions 1–3), Table 94-9**
9	Many anticancer medications demonstrate organ-specific toxicities, such as pulmonary fibrosis caused by bleomycin and transaminitis caused by cytarabine. Specific treatments for resolution of these toxicities do not exist; rather, supportive care for symptoms is necessary. If adverse effects do not resolve, discontinuation of therapy or dose modifications may be warranted.	**Case 94-10 (Questions 1–4), Case 94-11 (Question 1), Tables 94-10–94-13**
10	Many anticancer agents cause long-term complications after therapy, including treatment-related acute myeloid leukemia, lymphomas, bladder cancer, and bone sarcoma. The risks of secondary malignancies should be considered in assessing the adverse effect profile within the risks and benefits of specific types of therapy.	**Case 94-12 (Questions 1, 2)**
11	Cytotoxic chemotherapy is potentially gonadotoxic with use of specific agents. Sex, age, agent, and cumulative dose are factors in determining the risk of infertility. Methods of preserving fertility should be discussed with patients before initiating therapy.	**Case 94-13 (Question 1), Case 94-14 (Questions 1–3)**

Cytotoxic, targeted anticancer and immunotherapy agents are toxic to cancer cells and also to various host tissues and organs. The adverse effects of anticancer therapies are considered for both infusional and oral therapies and can be classified as common and acute toxicities, specific organ toxicities, and long-term complications. Common and acute toxicities generally occur as a result of inhibition of host-cell division. Host tissues most susceptible to cytotoxic agents include tissues with renewal cell populations, such as lymphoid tissues, bone marrow, and epithelium of the GI tract and skin. Some other common and acute toxicities (e.g., nausea and vomiting, hypersensitivity reactions) frequently occur in patients shortly after therapy. Specific organ toxicities often are attributed to a unique uptake or a selective toxicity of the anticancer agent to the organ. Long-term complications are toxicities that occur months to years after anticancer therapy. These long-term toxicities occur secondary to continued immunodeficiencies or from permanent damage to the organ cells from the specific therapy. Regardless of the type of toxicities observed, most are classified for severity by the National Cancer Institute (NCI) Common Terminology Criteria for Adverse Events. This classification creates a common method for classification of events in clinical trials and for management of toxicities that occur for patients receiving standard of care regimens.[1] These criteria may be accessed at the NCI website (**http://ctep.cancer.gov/protocolDevelopment/electronic_applications/ctc.htm**).

The toxicities associated with anticancer therapies are the most important factors limiting the use of potentially curative doses. Therefore, all discussions regarding the benefits of anticancer agents must include a discussion of toxicities associated with their use. Concerns regarding the toxicities of therapy include the incidence, predictability, severity, and reversibility of the adverse effects. In addition, the specific agent, dose intensity, and treatment duration can influence the incidence of several adverse effects. Although the incidence and predictability may be well defined in specific patient populations, the incidence often varies depending on individual susceptibility. The specific adverse effects that an individual patient will experience may be difficult to predict. Because several toxicities have well-defined characteristics, clinicians should be aware of the most common adverse effects.

Clinicians should also be aware of patient-specific factors, such as the stage of disease, concomitant illnesses, and concurrent medications, which could cause signs or symptoms that mimic the adverse effects associated with anticancer therapy. Many patients have disease involvement which may impair organ function. In addition, most patients with cancer receive many other medications, including antibiotics and analgesics, which may cause additional adverse effects or interact with anticancer agents. When a patient reports a new symptom, it may be difficult to determine whether it is secondary to anticancer therapy, concurrent medications, or disease progression.

COMMON AND ACUTE TOXICITIES

Hematologic Toxicities

The bone marrow contains a population of pluripotent stem cells capable of self-renewal and differentiation into any mature blood cell. Their progeny commits to either the myeloid or the lymphoid cell line. The myeloid stem cell further commits to developing into an erythrocyte (red blood cell (RBC)), megakaryocyte (platelet), or granulocyte (white blood cell (WBC)). Multiple types of granulocytes exist including neutrophils, basophils, and eosinophils, although neutrophils are the most common type.

After committing to a particular cell line, bone marrow precursor cells undergo a series of divisions (mitosis) to increase the number of cells. The cells then undergo several developmental stages to mature and differentiate into their final forms (postmitotic) and leave the bone marrow. The total time required for a cell to pass through the mitotic and postmitotic pool under normal resting conditions is approximately 10 to 14 days. This process is regulated by several cytokines; although many cytokines have been identified, only a few growth factors are now produced through recombinant DNA technology. These growth factors can expand the mitotic pool and accelerate maturation and differentiation. Ultimately, these growth factors decrease the total time spent in these stages to approximately 5 to 7 days.

The development and circulating life span of hematopoietic cell lines determine the severity of the depression of that cell line (nadir, lowest point) and the time course of peripheral cytopenias. Because RBCs survive approximately 120 days in the peripheral blood, clinically significant anemia is unlikely if production is impaired for a short period of time. Instead, anemia usually develops slowly after several courses of cytotoxic therapy. In contrast, platelets survive approximately 10 days, and granulocytes survive only 6 to 8 hours. Hence, neutropenia generally occurs before thrombocytopenia, but both may be observed after the first or subsequent courses of cytotoxic chemotherapy. The clinician may have to adjust the subsequent chemotherapy dosage based on nadir depth and slow recovery. Life-threatening neutropenia or thrombocytopenia often necessitates some action to minimize the risk of adverse effects with additional courses of cytotoxic chemotherapy. To diminish these effects, one can reduce the dose, delay therapy until recovery, or administer colony-stimulating factors (CSFs). The availability of CSFs provides an alternative approach to preventing severe neutropenia.

MYELOSUPPRESSION

CASE 94-1

QUESTION 1: J.T., a 68-year-old, 59-kg man with no significant past medical history, presents to the university hospital with complaints of cough and shortness of breath (SOB). Chest radiograph reveals a lesion in the right upper lobe; surgical resection and cytologic examination are positive for non-small-cell lung cancer (NSCLC). A workup for metastases is negative. J.T. is diagnosed with early-stage (stage II) NSCLC. His physicians plan to initiate adjuvant chemotherapy of carboplatin targeted to an area under the concentration–time curve (AUC) of 6 mg/mL × minute and paclitaxel 135 mg/m^2 on day 1. Discuss the toxicities that might be expected to occur with this regimen. What effects on the bone marrow can be anticipated and how might they clinically appear in J.T.? What factors can influence the incidence and severity of these adverse effects? When can J.T. expect these effects to occur?

Although several toxicities are commonly associated with carboplatin and paclitaxel, the most predictable and severe toxicity associated with this regimen is myelosuppression. This chemotherapy regimen can significantly affect any cell line, including RBCs, neutrophils, and platelets, and the cytopenias can cause significant morbidity or mortality. Decreased RBCs can cause anemia, and patients usually present with fatigue and decreased exercise tolerance. Having low neutrophil counts significantly increases a patient's risk for bacterial infections. Moreover, reduced platelets can cause thrombocytopenia, which can cause bleeding from the GI and genitourinary tracts.

Both patient-related and agent-related factors can significantly influence the degree of cytopenia a patient faces after cytotoxic therapy. Agent-related factors include the specific agent, dose intensity, and dose density. Because most anticancer treatments are not given as a single agent, the effects of concurrent cytotoxic therapies may intensify the myelosuppressive effect of an individual agent. Host factors that specifically may affect the cellularity of the bone marrow compartment also influence the degree of cytopenia. They include the following:

1. Patient age. Younger patients are generally better able to tolerate cytotoxic chemotherapy than elderly patients because they have a more cellular marrow with a decreased percentage of marrow fat.
2. Bone marrow reserve. Certain diseases might present with tumor cells in the bone marrow, such as leukemias and some lymphomas, in which case the bone marrow does not have a healthy reserve of normal hematopoietic cells to help in the recovery process.
3. The degree of myelosuppression from previous cytotoxic chemotherapy, radiation therapy, or both. Prior cytotoxic chemotherapy and radiation therapy to fields involving marrow-producing bone (pelvic bone and sternum) reduce bone marrow reserves.
4. The ability of the liver or kidney to metabolize and excrete the compounds administered. If agents are administered to patients with specific organ insufficiencies (i.e., renal or hepatic), slower clearance, resulting in increased systemic exposure, can occur. This can cause greater toxicities, including longer cytopenias.

These factors, along with the kinetics of the stem cells, can help clinicians predict the severity and duration of cytopenia observed after therapy.

With most myelosuppressive agents, the patient's WBC and platelet counts begin to fall within 5 to 7 days of cytotoxic therapy administration, reach a nadir within 7 to 10 days, and recover within 14 to 26 days. Phase-specific cytotoxic chemotherapy agents, such as the vinca alkaloids and antimetabolites, cause a fairly rapid onset of cytopenia that recovers faster than those occurring after treatment with phase-nonspecific agents, such as alkylating agents and anthracyclines. For poorly understood reasons, nitrosoureas typically produce severe, delayed neutropenia and thrombocytopenia 4 to 6 weeks after therapy. Other agents that exhibit this pattern include mitomycin and mechlorethamine. All of these anticancer agents exert their cytotoxic effects during the resting phase of the cell cycle. The nitrosoureas, as well as mitomycin and mechlorethamine, can cause two neutropenic nadirs; the first nadir occurs at the conventional time expected for phase-nonspecific agents and the second nadir occurs approximately 4 to 6 weeks after therapy. Many combination regimens with these agents are therefore given for 6-week cycles to avoid treatment before the second nadir. However, most other myelosuppressive regimens can be safely given every 3 to 4 weeks. The majority of the targeted therapies do not suppress bone marrow production, because they are designed to inhibit a specific molecular pathway rather than proliferating cells in general. Because of their minimal myelosuppressive effects, they may be desirable agents to add to regimens that are known to cause cytopenias.

Each of the agents included in J.T.'s regimen has marked myelosuppressive activity. His elderly age may place him at higher risk for exhibiting myelosuppression. J.T. should be carefully counseled to contact his physician or report to the emergency department if he experiences signs or symptoms of an infection (including fever) or bleeding. Typically, these symptoms occur 10 to 14 days after the first day of chemotherapy.

Prevention of Neutropenia

CASE 94-1, QUESTION 2: About 9 days after the first course of cytotoxic chemotherapy, J.T. experienced a severe sore throat and fever. He was admitted to the hospital and treated with intravenous (IV) antibiotics. At the time, his WBC count was 300 cells/μL; absolute neutrophil count (ANC), 50 cells/μL; platelets, 102,000 cells/μL; and hemoglobin (Hgb), 11 g/dL. His fever resolved after 3 days, and all cultures were negative for bacterial growth. It is now 3 weeks after chemotherapy, and he is scheduled to receive a second course. Should he receive the same doses he was given initially?

One option would be to reduce (usually by 25%) the dose of each agent for all subsequent cycles. Although a dose reduction can clearly cause less neutropenia, it can also compromise the response and survival of patients with chemotherapy-sensitive tumors. Because J.T.'s cancer (i.e., early-stage NSCLC) is both chemosensitive and potentially curable, a dosage reduction is undesirable. To minimize the risk of neutropenia with future therapy, CSFs can be administered to J.T. to prevent potential complications associated with neutropenia.

Prophylactic administration of CSFs can be used to reduce the myelosuppressive effects of cytotoxic chemotherapy. Several CSFs—granulocyte colony-stimulating factors (G-CSFs [filgrastim, tbo-filgrastim, and filgrastim-sndz]), granulocyte-macrophage colony-stimulating factor (GM-CSF [sargramostim]), and a pegylated long-acting form of filgrastim, pegfilgrastim—are available in the United States.

Pegfilgrastim was developed with the aim of providing the same pharmacologic benefit as filgrastim while offering the advantage and convenience of fewer injections. The FDA approved filgrastim-sndz as the first biosimilar in the United States in March 2015. Although tbo-filgrastim was FDA-approved in 2012, it is not considered a biosimilar because it was filed as a Biologics License Application, prior to the establishment of the FDA biologics approval pathway. Clinical safety, particularly related to immunogenicity, is a concern with new approval of biosimilars, and assessment of tolerability and safety should occur in clinical practice.[2] The evidence-based clinical practice guidelines for the use of CSFs have been developed by the American Society of Clinical Oncology (ASCO).[3] These guidelines recommend primary prophylaxis for all patients receiving chemotherapy regimens that have been previously reported to cause a febrile neutropenia incidence of approximately 20%. A CSF used in these patients can reduce both the incidence of febrile neutropenia and need for hospitalizations and broad-spectrum antibiotics. However, CSF usage has not been shown to lead to better tumor response or higher overall survival. Two randomized Phase III clinical trials have shown that the risk of neutropenic fever is reduced when primary prophylaxis is used in regimens with a known neutropenia incidence of approximately 20%. In one trial, 928 patients with breast cancer receiving docetaxel 100 mg/m^2 every 21 days were randomly assigned to receive placebo or pegfilgrastim 6 mg subcutaneously (SC) 24 hours after chemotherapy. Patients who received pegfilgrastim had a lower incidence of febrile neutropenia (1% vs. 17%, respectively) and hospitalizations (1% vs. 14%, respectively).[4] A trial in patients (n = 171) with small-cell lung cancer (SCLC) receiving a dose-intense regimen containing cyclophosphamide 1,000 mg/m^2 on day 1, doxorubicin 45 mg/m^2 on day 1, and etoposide 100 mg/m^2 on days 1 to 3 every 21 days was conducted. Patients were randomly assigned to receive prophylactic antibiotics with or without filgrastim. The rate of febrile neutropenia over all five cycles was 32% with prophylactic antibiotics without filgrastim versus 18% with antibiotics and filgrastim.[5] A meta-analysis of 17 randomized trials including 3,493 adult patients with solid tumors and lymphomas showed that the use of filgrastim as primary prophylaxis reduced the risk of febrile neutropenia and improved the rate of full-dose cytotoxic chemotherapy given on schedule. Additionally, the investigators in the meta-analysis observed a significant reduction in the risk of infection-related mortality.[6] The use of CSFs for secondary prophylaxis is recommended by ASCO for those patients who experience a neutropenic complication from the prior cycle, where primary CSF was not used, when a reduced dose or treatment delay may negatively impact the survival/treatment outcome.[3] Because the regimen J.T. received does not typically produce a 20% incidence of febrile neutropenia, a CSF was not recommended for him after his first course of cytotoxic chemotherapy. Now that J.T. has experienced febrile neutropenia and he has a potentially curable malignancy, a CSF is indicated with subsequent courses of chemotherapy to prevent additional febrile episodes.

Dosing of Colony-Stimulating Factors

CASE 94-1, QUESTION 3: How should a CSF be dosed in J.T. to reduce the severity of chemotherapy-induced neutropenia?

The recommended initial dose of filgrastim, tbo-filgrastim or filgrastim-sndz, is 5 mcg/kg/day as a single daily subcutaneous (SC) injection, and of sargramostim, 250 mcg/m^2/day SC beginning 24 to 72 hours following the administration of myelotoxic chemotherapy. The ASCO guidelines state that rounding the dose of either weight-based filgrastim or sargramostim to the nearest vial size may enhance patient convenience and reduce cost without clinical detriment. Because commercially available vials or syringes contain either 300 or 480 mcg of filgrastim, adult patients weighing less than 75 kg should receive 300 mcg daily and adult patients weighing more than 75 kg should receive 480 mcg daily.[3] Because of differences in commercially available vial sizes, the weight break point for sargramostim is slightly different; patients who weigh more than 60 kg should receive 500 mcg daily and patients who weigh less than 60 kg should receive 250 mcg daily. Pegfilgrastim is given once per cycle, 24 to 72 hours following administration of myelotoxic chemotherapy and not less than 14 days prior to the next treatment, as 6 mg SC in adult patients regardless of patient weight. A new formulation of pegfilgrastim was recently approved that is a timed automated-inject device that delivers the medication 27 hours after it is activated.[7]

The ASCO guidelines also recommend a shorter duration of treatment than the manufacturers. The manufacturers recommend that therapy with filgrastim or sargramostim continues until the patient's neutrophil count is greater than 10,000 cells/µL after the expected chemotherapy nadir. This is based on the observation that the neutrophil count falls roughly 50% after discontinuing a CSF. The risk of bacterial infection is highest, however, in patients with neutrophil counts of less than 500 to 1,000 cells/µL; patients with neutrophil counts greater than that are not thought to be at high risk for experiencing bacterial infections. Thus, many clinicians elect to discontinue the CSF when the neutrophil count reaches 2,000 to 4,000 cells/µL after the chemotherapy nadir. This reduces the number of treatment days and the cost associated with therapy while concurrently reducing the excessive risk for bacterial infections. The ASCO guidelines support this recommendation to discontinue CSF earlier.

In summary, J.T. should be given either filgrastim, tbo-filgrastim or filgrastim-sndz 300 mcg/day, or sargramostim 250 mcg/day SC beginning the day after his last dose of chemotherapy. Treatment should continue until the ANC is greater than 2,000 to 4,000 cells/µL. Filgrastim is used much more widely than sargramostim. Alternatively, J.T. could receive a single 6-mg injection of pegfilgrastim the day after chemotherapy administration. This more convenient administration is due to pegfilgrastim's favorable pharmacokinetics. Self-regulation of pegfilgrastim serum levels, related to its pegylation, is almost entirely dependent on neutrophil receptor-mediated clearance. Serum levels of pegfilgrastim will remain elevated during neutropenia induced by chemotherapy, and decline on recovery of neutrophil counts.[8] Aside from high cost and inconvenience, the only negative effect of filgrastim or sargramostim therapy is mild transient bone pain. Bone pain is most commonly experienced when patients begin to recover peripheral blood cells after their nadir. The proposed mechanism suggests the stimulatory effect of CSF on granulopoiesis causes the pain. Most patients commonly report pain in bone marrow-rich areas, such as the sternum and pelvic regions. They should be advised that the bone pain experienced during marrow recovery is normal and usually is relieved with analgesic agents.

Treatment of Fever and Neutropenia with a Colony-Stimulating Factor

CASE 94-1, QUESTION 4: If J.T. was not given filgrastim and presented with febrile neutropenia, would CSF therapy be helpful?

Febrile neutropenia leads to increased hospital admissions and lengths of stay as well as greater morbidity and mortality, so the optimal indication for CSFs is as prophylaxis; however, CSFs have been studied as part of the treatment of neutropenic fever. Because the duration of neutropenia is the most significant prognostic factor in patients with established febrile neutropenia, the major benefit of CSFs is their ability to reduce the duration of neutropenia. CSFs accelerate hematopoiesis by expanding the mitotic pool of committed progenitor cells and shortening the time spent in the postmitotic pool from 6 days to 1 day. If CSFs reduce the duration of neutropenia in patients who present with febrile neutropenia, then morbidity, mortality, and cost should be significantly reduced.

The ability of CSFs to reduce the duration of neutropenia in patients with established febrile neutropenia has been addressed in numerous randomized, double-blind, placebo-controlled trials[9] and two meta-analyses.[3,10,11] The combined data for filgrastim and sargramostim reveal minimal-to-moderate benefit in reducing hospital stays and no differences in mortality. Furthermore, questions have been raised as to whether all patients with febrile neutropenia require hospitalization. Several studies have shown equal efficacy and safety with increased cost effectiveness of outpatient treatment of febrile neutropenia.[12–14] Although CSFs do appear to hasten neutrophil recovery, the true cost–benefit ratio associated with the use of these products in established febrile neutropenia remains to be determined. The ASCO guidelines currently do not support routine use of CSFs in patients with febrile neutropenia, although they do recognize that certain patients with febrile neutropenia and high-risk features predictive of clinical deterioration (e.g., age >65 years, pneumonia, fungal infection, hypotension, sepsis syndrome, uncontrolled primary disease) may benefit from use of CSFs.[3]

Thrombocytopenia

The reduction in platelets is another common myelosuppressive toxicity seen with chemotherapy. Most commonly, thrombocytopenia is managed via the use of platelet transfusions and modifications to the chemotherapy dosing scheme. Although oprelvekin, a thrombopoietic growth factor, is indicated to prevent severe thrombocytopenia and reduce the need for platelet transfusions after myelosuppressive chemotherapy in patients with nonmyeloid malignancies at high risk for developing severe thrombocytopenia, it is rarely utilized in clinical practice due to limited efficacy and potential adverse effects.[15,16] The majority of clinicians do not incorporate the use of oprelvekin into care for patients with chemotherapy-induced thrombocytopenia, and use is not considered part of the standard of care. The use of thrombopoietin receptor agonists, romiplostim and eltrombopag, is being investigated. These agents are both approved for the treatment of idiopathic thrombocytopenia purpura (ITP), but only case reports and Phase I trials have looked at the use of these agents for chemotherapy-induced thrombocytopenia[17] and are not to be utilized in this setting.

Anemia

Anemia usually is not a dose-limiting toxicity commonly associated with cytotoxic chemotherapy, because RBCs survive approximately 120 days. Chemotherapy predominantly affects RBCs by causing anisocytosis and macrocytosis. These effects are related to inhibition of DNA synthesis, and they predominantly occur after treatment with antimetabolites, including folic acid analogs, hydroxyurea, purine antagonists, and pyrimidine antagonists. Anemia commonly does not accompany these changes in RBC size. In addition, chemotherapy-induced effects on RBCs are rarely the sole factor contributing to the low Hgb levels that necessitate an RBC transfusion. See Chapter 92, Anemias, for additional information on anemias and their treatment.

COAGULOPATHIES

Patients with cancer can exhibit bleeding secondary to chemotherapy-induced thrombocytopenia or thrombosis after chemotherapy. Bleeding can occur after treatment with asparaginase or the pegylated formulation, pegaspargase, due to inhibition of the synthesis of fibrinogen and other specific coagulation factors produced by the liver under the influence of vitamin K.[18–20] Asparaginase has a widespread effect on protein synthesis, and many plasma protein factors are depressed shortly after treatment. A patient receiving asparaginase can often exhibit a prolonged prothrombin time (PT) and partial thromboplastin time (PTT). Bleeding or thrombosis occurring as a direct result of changes in coagulation factors has not been frequently reported or conclusively documented. Coagulation factors may return to normal levels with continued administration of the agent, which suggests that the impairment of protein synthesis created by asparaginase is partially overcome by the liver. Specific treatment of prolonged PT and PTT with coagulation factors, fibrinogen, or vitamin K is not indicated.[21]

Thrombotic Events

The risk of venous thrombotic events is markedly elevated in patients with cancer. Possible pathophysiologic mechanisms include hypercoagulability marked by abnormalities in clotting factors and the coagulation cascade, vessel wall damage, and vessel wall compression by tumor masses. Many risk factors for thromboembolic events include the type of cancer, stage of cancer, comorbidities, mobility, and type of systemic anticancer therapy received, among others. Pancreatic, stomach, kidney, lung, brain, and uterine cancers are associated with the highest risk.[22] Use of systemic anticancer therapy has been associated with a 2.2-fold increased risk compared with patients not using these treatment modalities.[23]

Trousseau[24] first reported an increased incidence of venous thrombosis in patients with cancer, and many investigators have since confirmed the relationship of multiple or migratory venous thrombosis in patients with cancer. Up to one-third of apparently healthy adults who exhibit otherwise unexplained deep vein thrombosis eventually are proved to have a malignancy.[25,26]

Initiating treatment for acute promyelocytic leukemia (APL) commonly is associated with disseminated intravascular coagulation (DIC).[27,28] DIC is a systemic process that results from a large activation of the clotting cascade and presents as overlapping bleeding and thrombotic events. These events can result in end-organ damage. The lysed tumor cells in patients with APL appear to release procoagulant materials after anticancer therapy causing both hemorrhagic and thrombotic events. The foundation of treatment for DIC is to treat the underlying disease. Use of heparin and antifibrinolytics to minimize risk of coagulation is controversial. Other treatment is primarily supportive with blood products including platelets and cryoprecipitate.[28]

Several anticancer agents have been associated with an increased thrombosis risk, including cytotoxic chemotherapy (cisplatin, fluorouracil), hormonal targets (tamoxifen, aromatase inhibitors), antiangiogenic therapies (bevacizumab), and the immunomodulatory agents, thalidomide and lenalidomide.[29] Thalidomide and lenalidomide, in combination with other agents including dexamethasone and doxorubicin, have been associated with venous thromboembolic events when used in the treatment of multiple myeloma and other diseases.[30–32] Prophylaxis is warranted

---

when these combinations are used. There are several guidelines and reviews discussing both prophylaxis, including the use of low-molecular-weight heparin or warfarin, and treatment in this patient population.[30] The use of direct-acting oral anticoagulants such as rivaroxaban or apixaban is not well studied nor currently recommended for prophylaxis in this population. Bevacizumab is associated with both arterial thrombosis and bleeding events. A retrospective analysis of five trials of patients receiving chemotherapy for colorectal, breast, or NSCLC showed a 3.8% incidence of arterial thrombosis in patients receiving chemotherapy and bevacizumab versus 1.7% in chemotherapy alone.[33] Most bleeding events associated with bevacizumab are minor. However, severe major bleeding events have been reported in patients with metastatic colorectal and lung cancer.[34] Different types of thrombotic events have been identified in patients receiving bevacizumab for other types of cancers.[35]

Other factors can cause patients to experience thrombosis. Many patients receiving cancer chemotherapy often have other illnesses that may predispose them to exhibiting thrombosis. In addition, surgical procedures and bed rest can increase the risk of thrombosis. Clinicians should maintain a high index of suspicion when a patient with cancer presents with signs or symptoms of thrombosis. Several reviews summarize risk factors and recommendations and provide further insight for specific clinical scenarios.[30,36,37]

Gastrointestinal Tract Toxicities

The GI tract may be second only to bone marrow in its susceptibility to toxic effects produced by cytotoxic chemotherapy. GI toxicities include nausea and vomiting, oral complications, esophagitis, and lower bowel disturbances.

NAUSEA AND VOMITING

Nausea and vomiting are common and serious toxicities associated with many cytotoxic and targeted anticancer agents. Anticancer agents or their metabolites may stimulate dopamine or serotonin receptors in the GI tract, the chemoreceptor trigger zone, or the CNS, which ultimately act on the vomiting center. Emesis most commonly occurs on the first day of chemotherapy and often persists for several days thereafter.[38] Most patients who receive traditional cytotoxic chemotherapy agents require antiemetics before and after chemotherapy for several days to control these symptoms. The most appropriate antiemetic regimen is based on patient-specific and agent-specific factors. Some of the targeted therapy agents carry some risk of emetogenicity, although it is generally milder. Guidelines are beginning to incorporate these targeted agents into their emetogenic classification schema based on incidence of nausea and vomiting in clinical trials (see Chapter 22, Nausea and Vomiting, for antiemetic algorithms and emetogenic potential of the cancer agents).

COMPLICATIONS OF THE ORAL CAVITY

Complications of the oral cavity include mucositis (or stomatitis), xerostomia (dry mouth), infection, and bleeding. The incidence of severe oral mucositis varies with the anticancer therapies given. Doxorubicin and continuous-infusion fluorouracil are among the agents at highest risk for causing severe mucositis. Virtually, all patients who receive myeloablative hematopoietic cell transplantation (HCT) or have radiation therapy to the head and neck experience oral complications.[39] These toxicities occur because of the nonspecific effects of chemotherapy on cells undergoing rapid division, including the cells of the mouth that undergo rapid renewal with a turnover time equal to 7 to 14 days. Cytotoxic therapy reduces the renewal rate of the basal epithelium and can cause mucosal atrophy, as well as glandular and collagen degeneration.[39,10] Radiation therapy to the head and neck also causes mucosal atrophy by decreasing cell renewal. Radiation can also cause fibrosis of the salivary glands, muscles, ligaments, and blood vessels, and damage to the taste buds.[40] The combined effects of chemotherapy and radiation therapy on the oral mucosa can also cause infection and bleeding in the oral cavity. Infection and bleeding occurs when treatment causes bone marrow suppression, including thrombocytopenia and neutropenia. Because the oral mucosa is highly vascular and frequently traumatized, bleeding occurs commonly with thrombocytopenia. In addition, cytotoxic chemotherapy and neutropenia can alter the extensive microbial flora harbored in the oral cavity, thus leading to oral infections. Oral complications often compound one another. For example, xerostomia can accelerate the development of mucositis as well as the formation of dental caries and local infection. Mucositis can clearly predispose the oral cavity to local bleeding and infection, as well as systemic infections leading to sepsis. These oral complications can also cause varying degrees of discomfort and adversely affect the patient's ability to eat, which potentially may lead to a compromised nutritional status. Topical treatments of oral complications are reviewed extensively in guidelines.[41]

Xerostomia

CASE 94-2

QUESTION 1: J.B. is a 55-year-old man with newly diagnosed, locally advanced head and neck cancer. His planned therapy includes cisplatin and fluorouracil given with concurrent radiation for a total of 6 weeks after surgical resection. A review of systems suggests that J.B. has poor oral hygiene, and a decision is made to consult the dental department of the university hospital before initiating radiation and chemotherapy. Is J.B. at risk for experiencing oral complications of chemotherapy? Is there anything that should be completed at this point to decrease his risk?

J.B. is at high risk for several of the oral complications previously described. Xerostomia, one of the most frequent side effects of radiation therapy to the head and neck, occurs secondary to radiation-induced changes to the salivary glands.[42] Evidence supports a direct relationship between the dose of radiation to the salivary glands and the extent of glandular changes.[43] In most patients treated with less than 6,000 rad (radiation absorbed dose), radiation-induced changes to the salivary glands are reversible within 6 to 12 months after the end of therapy. J.B. will also be receiving chemotherapy agents (i.e., cisplatin) that can cause xerostomia and enhance the toxicity to the salivary glands. Clinically, xerostomia has been caused by as little as two to three radiation doses of 200 rad.[43]

Damage to the salivary glands causes various effects, including a loss of salivary buffering capacity, lower salivary pH, no mechanical flushing, decreased salivary immunoglobulin A, and reduction of saliva production. In addition, xerostomia can alter the sense of taste, causing some patients to lose their ability to differentiate between sweet and salty foods and others to report a bitter taste. Xerostomia also commonly causes caries. Caries and decalcification may become sufficiently severe to compromise tooth integrity and cause fracture. Because saliva is no longer available to help clear bacteria from the mouth, xerostomia also predisposes patients to infection secondary to the increases in oral bacteria.

Treatments and Prevention

Amifostine, an organic thiophosphate chemoprotectant agent, is approved to reduce the incidence of moderate-to-severe xerostomia in patients having postoperative radiation treatment for head and neck cancer. Guidelines published by ASCO support the use of amifostine to reduce the incidence of acute and late xerostomia in patients receiving fractionated radiation therapy without concurrent chemotherapy for head and neck cancer.[44] However, amifostine is not widely used due to its cost and adverse effect profile. If xerostomia occurs, treatment strategies can include stimulation of existing salivary flow and replacement of lost secretions. Relatively low doses of systemically administered pilocarpine (5–10 mg orally 3 times daily) may stimulate salivary flow and produce clinically significant benefits in patients with postradiation xerostomia.[45] Results demonstrating pilocarpine's benefit are inconsistent. Dose-related adverse effects include cholinergic effects, such as sweating, rhinitis, headache, nausea, and abdominal cramps. A review on the oral complications of cancer therapy suggests that cevimeline (30 mg orally 3 times daily) and bethanechol (25 mg orally 3 times daily) may have fewer side effects than those seen with pilocarpine.[42] Sucrose-free hard candy and sugar-free chewing gum can also stimulate salivation, but these treatments are typically considered oral comfort agents. Saliva substitutes can also provide oral comfort to patients with xerostomia. Commercially available saliva substitutes generally are recommended for use before meals and at bedtime. They are available in several formulations, including sprays, rinses, and chewing gums. Patients who find one product or formulation unacceptable or unsuccessful may benefit from experimenting with other formulations or product lines. Studies have shown that salivary substitutes containing carboxymethyl cellulose or hydroxyethyl cellulose are more effective in relieving dryness than water-based or glycerin-based solutions.[46,47]
